To so many fine memories of my mother Ashraf, my father
Mohammad, and my brother Mohsen, for their uncompromising
belief in the power of education.

About the Editor-in-Chief

Hossein Bidgoli, Ph.D., is professor of Management Information Systems at California State University. Dr. Bidgoli helped set up the first PC lab in the United States. He is the author of 43 textbooks, 27 manuals, and over five dozen technical articles and papers on various aspects of computer applications, information systems and network security, e-commerce, and decision support systems published and presented throughout the world. Dr. Bidgoli also serves as the editor-in-chief of *The Internet*

Encyclopedia, *The Handbook of Information Security*, and *The Encyclopedia of Information Systems*.

The Encyclopedia of Information Systems was the recipient of one of the Library Journal's Best Reference Sources for 2002 and *The Internet Encyclopedia* was recipient of one of the PSP Awards (Professional and Scholarly Publishing), 2004. Dr. Bidgoli was selected as the California State University, Bakersfield's 2001–2002 Professor of the Year.

Contents

Contributors	xvii	Video Compression	227
Preface	xxiii	<i>Immanuel Freedman</i>	
Guide to The Handbook of Computer Networks	xxvi	Speech and Audio Compression	268
Reviewers List	959	<i>Peter Kroon</i>	
Index	969	Multimedia Streaming	282
		<i>Nabil J. Sarhan</i>	
Volume I: Key Concepts, Data Transmission, and Digital and Optical Networks		High-Definition Television	293
		<i>Jim Krause</i>	
Part 1: Key Concepts		Part 2: Hardware, Media, and Data Transmission	
The Telecommunications Industry	3	Modems	309
<i>David G. Loomis</i>		<i>Darren B. Nicholson and Jennifer A. Nicholson</i>	
Data Communications Basics	19	Conducted Communications Media	320
<i>Hossein Bidgoli</i>		<i>Thomas L. Pigg</i>	
Data-Link Layer Protocols	30	Wireless Channels	334
<i>Stefan Joe-Yen and Chadwick Sessions</i>		<i>Okechukwu C. Ugweje</i>	
Network Layer Protocols	40	Sources of Errors, Prevention, Detection, and Correction	352
<i>Muhannad Harrim, Mohamed El-Wakil, and Ala Al-Fuqaha</i>		<i>Syed H. Murshid and Azhar M. Khayrattee</i>	
Transport Layer Protocols	63	Routers	364
<i>Vassilis Tsaoussidis</i>		<i>Min Song</i>	
Session, Presentation, and Application Layer Protocols	76	Switches	375
<i>Chadwick Sessions</i>		<i>Min Song</i>	
Digital Transmission	84	Bridges	390
<i>Marvi Teixeira and Viktor Zaharov</i>		<i>Zartash Afzal Uzmi and Tariq Mahmood Jadoon</i>	
Analog Transmission	102	Pulse Amplitude Modulation	403
<i>Hamidreza Saligheh, Joonhyuk Kang, Jaehak Chung, and Vahid Tarokh</i>		<i>Muneo Fukaishi</i>	
Voice Communications Systems: KTS, PBX, Centrex, and ACD	115	Frequency and Phase Modulation	414
<i>Hassan Ibrahim</i>		<i>Albert Lozano-Nieto</i>	
Messaging Systems: Facsimile and Voice Processing	127	Carrierless Amplitude Phase Modulation	426
<i>Albert K.S. Wong, Nan Zhang, and Xu Yan</i>		<i>Tim Collins</i>	
Public Switched Telephone Network	158	Minimum Shift Keying	438
<i>Jingxuan Liu and Nirwan Ansari</i>		<i>Tao Jiang</i>	
Information Theory	178	Optical Differential Phase Shift Keying	455
<i>David Blockus and Mark Stamp</i>		<i>Xiang Liu</i>	
Data Compression	199	DMT Modulation	473
<i>Chang-Su Kim and C.C. Jay Kuo</i>		<i>Stephan Pfletschinger</i>	
Image Compression	212	Pulse Position Modulation	492
<i>Alfred Mertins</i>		<i>Jon Hamkins</i>	

Digital Phase Modulation and Demodulation	509	Fiber-Optic Filters and Multiplexers	850
<i>Zartash Afzal Uzmi</i>		<i>Hamid Hemmati</i>	
Line Coding	522	Optical Solitons	861
<i>Asim Loan</i>		<i>Natalia M. Litchinitser</i>	
Spread Spectrum	538	Synchronous Optical Code Division Multiplexing Systems	885
<i>Murad Hizlan</i>		<i>Hideyuki Sotobayashi</i>	
Frequency Division Multiplexing	553	Free-Space Optics	900
<i>Zhu Liu</i>		<i>John Liu and Mark Schaefer</i>	
Time Division Multiplexing	568	Optical Switching Techniques in WDM Optical Networks	909
<i>William A. Shay</i>		<i>Amor Lazzez, Nouredine Boudriga, and Mohammad S. Obaidat</i>	
Statistical Time Division Multiplexing	579	SONET and SDH Networks	929
<i>Kavitha Chandra</i>		<i>M. Farooque Mesiya</i>	
Orthogonal Frequency Division Multiplexing	591	Passive Optical Networks for Broadband Access	948
<i>Shinsuke Hara</i>		<i>Nirwan Ansari and Yuanqiu Luo</i>	
Wavelength Division Multiplexing	606		
<i>Yassine Khelifi, Nouredine Boudriga, and Mohammad S. Obaidat</i>			
 Part 3: Digital and Optical Networks		 Volume II: LANs, MANs, WANs, The Internet, and Global, Cellular, and Wireless Networks	
Digital Communication Basics	629	Part 1: LANs, MANs, and WANs	
<i>Robert W. Heath and Atul A. Salvekar</i>		Local Area Networks	3
Digital Radio Broadcasting	642	<i>Wayne C. Summers</i>	
<i>Zhuojun Joyce Chen</i>		Ethernet LANs	19
Spread Spectrum Signals for Digital Communications	675	<i>William Stallings</i>	
<i>Filippo Giannetti and Marco Luise</i>		Token Ring LANs	27
Optical Fiber Communications	692	<i>Norman C. Strole, Werner Bux, and Robert D. Love</i>	
<i>Habib Hamam and Sghaier Guizani</i>		Optical Fiber LANs	40
Optical Transmitters, Receivers, and Noise	708	<i>Mo Adda, Amanda Peart, and Jau Ming Chew</i>	
<i>Ken Pedrotti</i>		Windows 2000 Operating System	57
Optical Signal Regeneration	729	<i>Dario Forte</i>	
<i>Mingshan Zhao</i>		Linux Operating System	78
Optical Sources	745	<i>Mark Shacklette</i>	
<i>Tin Win and Serge Demidenko</i>		Metropolitan Area Networks	91
Lambda and Sub-Lambda Switching	767	<i>Richard J. Nieporent</i>	
<i>Mario Baldi and Yoram Ofek</i>		Terrestrial Wide Area Networks	116
Optical Cross Connects	783	<i>Gurdeep Singh Hura</i>	
<i>Wen-De Zhong</i>		Packet Switching	136
Optical Memories	795	<i>Qinqing Zhang and Qi Bi</i>	
<i>Paul W. Nutter</i>		Circuit Switching	146
Characterization of Optical Fibers	815	<i>Farid Farahmand and Qiong (Jo) Zhang</i>	
<i>Liang Chen, John Cameron, and Xiaoyi Bao</i>			
Optical Couplers and Splitters	828		
<i>Kais Dridi, Mustapha Razzak, and Habib Hamam</i>			

Message Switching	159	Voice Over Internet Protocol	468
<i>Farid Farahmand</i>		<i>Sherali Zeadally and Farhan Siddiqui</i>	
Frame Relay	172	Signaling Approaches	488
<i>Eddie Rabinovitch</i>		<i>Edmundo Monteiro, Fernando Boavida, Marilia Curado, and Luís Cordeiro</i>	
Asynchronous Transfer Mode (ATM)	183	Voice over MPLS and VoIP over MPLS	509
<i>Arjan Durresi and Raj Jain</i>		<i>Junaid Ahmed Zubairi</i>	
Broadband Integrated Services Digital Network	200	Telephone Number Mapping (ENUM)	519
<i>B. Muthukumaran</i>		<i>Leslie L. Daigle</i>	
DSL (Digital Subscriber Line)	210	Web Hosting	532
<i>Milos Milosevic</i>		<i>Thomas C. Bressoud</i>	
Cable Modems	221	End-System QoS	545
<i>Shaheed N. Mohammed</i>		<i>Tarek F. Abdelzhaer and Chengdu Huang</i>	
Home Networking	230	Web Services	559
<i>Sherali Zeadally</i>		<i>Mei-Ling L. Liu</i>	
Multimedia Networking	246		
<i>Hans-Peter Dommel</i>			

Part 2: The Internet, Global Networks, and VoIP

The Internet Fundamentals	267
<i>Hossein Bidgoli</i>	
History of the Internet	280
<i>John Lucas Sherry and Nicholas David Bowman</i>	
Internet2®	294
<i>Linda Bruenjes and Carolyn Siccama</i>	
Internet Domain Name System	305
<i>Krishna Jayakar</i>	
Information Retrieval on the Internet	320
<i>Raymond F. Wisman</i>	
Internet Architecture	345
<i>Geoffrey G. Xie</i>	
TCP/IP Suite	358
<i>Prabhaker Mateti</i>	
SMTP (Simple Mail Transfer Protocol)	388
<i>Vladimir V. Riabov</i>	
IP Multicast	407
<i>Emilia Rosti</i>	
Network QoS	417
<i>Ying Lu</i>	
Internet Security Standards	428
<i>Raymond R. Panko</i>	
Technology and Standards for Low-Bit-Rate Vocoding Methods	447
<i>Miguel Arjona Ramírez and Mário Minami</i>	

Part 3: Cellular and Wireless Networks

Cellular Communications Channels	579
<i>Aarne Mämmelä and Risto Wichman</i>	
Cellular Telephony	591
<i>Elyes Ben Ali Bdira</i>	
Mobile Radio Communications	616
<i>Chi Zhou</i>	
Evolution of Mobile Cellular Networks	630
<i>Jiang Xie and Xiaoyuan Gu</i>	
Global System for Mobile Communications	642
<i>Mohamed A. Haleem and Koduvayur P. Subbalakshmi</i>	
General Packet Radio Service	658
<i>Allen H. Levesque</i>	
Location Management in Personal Communication Systems	675
<i>Jingyuan Zhang and Ivan Stojmenovic</i>	
Mobility Management in Heterogeneous Networks	685
<i>Guangbin Fan, Xuming Lu, and Song Ci</i>	
Universal Mobile Telecommunications System	699
<i>Faouzi Zarai, Noureddine Boudriga, and Mohammad S. Obaidat</i>	
International Mobile Telecommunications-2000 and 3G Wireless Systems	716
<i>Mustafa M. Matalgah and Omar M. Hammouri</i>	
Code Division Multiple Access (CDMA)	751
<i>Frank H.P. Fitzek and Marcos Katz</i>	

Time-Division Multiple Access	769	Data Monitoring and Gathering in Sensor Networks	1113
<i>Tom S. Chan</i>		<i>Symeon Papavassiliou, Stella Kafetzoglou, and Jin Zhu</i>	
Carrier Sense Multiple Access Protocols	779	In-Network Data Aggregation in Wireless Sensor Networks	1131
<i>Wei Ye</i>		<i>Kemal Akkaya and Ismail Ari</i>	
Bluetooth Technology	790	Cognitive and Software Defined Radios for Dynamic Spectrum Access	1147
<i>Brent A. Miller</i>		<i>Troy Weingart and Douglas C. Sicker</i>	
Satellite Communications Basics	802	Localization in Wireless Networks	1158
<i>Michele Luglio and Antonio Saitto</i>		<i>Slim Rekhis, Noureddine Boudriga, and Mohammad S. Obaidat</i>	
Land-Mobile Satellite Channel	815	Interference Management in Wireless Networks	1178
<i>Emilio Matricciani</i>		<i>Keivan Navaie and Shahrokh Valaee</i>	
Geosynchronous Fixed Satellite Communications	836	Wireless Wide Area Networks	1191
<i>Michele Luglio and Antonio Saitto</i>		<i>Anthony H. Smith and Raymond A. Hansen</i>	
Satellites in IP Networks	860	Wireless Broadband Access	1200
<i>Fatih Alagöz and Abbas Jamalipour</i>		<i>Hsiao-Hwa Chen and Mohsen Guizani</i>	
Global Navigation Satellite Systems	877	Indoor Wireless Infrared Communications	1223
<i>Omar Al-Bayari and Balqies Sadoun</i>		<i>Z. Ghassemlooy</i>	
Wireless LANs	896		
<i>Mohammad S. Obaidat, G. I. Papadimitriou, and S. Obaidat</i>			
Wireless LAN Standards	917		
<i>Prashant Krishnamurthy</i>			
Bit-Interleaved Coded Modulation	935		
<i>Yuheng Huang and James A. Ritcey</i>			
The Wireless Application Protocol	955		
<i>Lillian N. Cassel and Arun Srinivasa Murthy</i>			
Wireless ATM	972		
<i>Amel Meddeb and Noureddine Boudriga</i>			
Wireless IP Telephony	991		
<i>Manish Marwah and Shivakant Mishra</i>			
Wireless Internet	1000		
<i>Abbas Jamalipour</i>			
Internetworking of Heterogeneous Wireless Networks	1018		
<i>Sherali Zeadally and Farhan Siddiqui</i>			
Principles and Applications of Ad Hoc and Sensor Networks	1040		
<i>Marco Conti</i>			
Medium Access in Ad Hoc and Sensor Networks	1057		
<i>Vojislav B. Mišić and Jelena Mišić</i>			
Emerging Trends in Routing Protocols in Mobile Wireless Ad Hoc and Sensor Networks	1084		
<i>Jamal N. Al-Karaki</i>			
Broadcasting in Ad Hoc and Sensor Networks	1101		
<i>François Ingelrest, David Simplot-Ryl, Hong Guo, and Ivan Stojmenović</i>			
		Volume III: Distributed Networks, Network Planning, Control, Management, and New Trends and Applications	
		Part 1: Distributed Networks	
		Client/Server Computing Basics	3
		<i>Daniel McFarland and Darren B. Nicholson</i>	
		Groupware	16
		<i>Robert Slagter</i>	
		Network Middleware	33
		<i>Linda Volonino and Pragati Dalal</i>	
		Grid Computing Fundamentals	45
		<i>Mark Baker</i>	
		Grid Computing Implementation	63
		<i>Barry Wilkinson and Clayton Ferner</i>	
		Cluster Computing Fundamentals	79
		<i>Hong Ong and Mark Baker</i>	
		Next-Generation Cluster Networks	93
		<i>Keren Bergman, Benjamin A. Small, and Larry A. Bergman</i>	
		Utility Computing on Global Grids	110
		<i>Chee Shin Yeo, Rajkumar Buyya, Marcos Dias de Assunção, Jia Yu, Anthony Sulistio, Srikumar Venugopal, and Martin Placek</i>	

Peer-to-Peer Network Architecture	131	Computer Viruses and Worms	440
<i>Jing Wu and Michel Savoie</i>		<i>Robert Slade</i>	
Peer-to-Peer Network Applications	152	Denial of Service Attacks	454
<i>Stan Kurkovsky</i>		<i>Qijun Gu and Peng Liu</i>	
Incentive Issues in Peer-to-Peer Systems	168	E-Mail Threats and Vulnerabilities	469
<i>Yu-Kwong Kwok</i>		<i>David Harley</i>	
Storage Area Network Fundamentals	189	Virtual Private Networks	488
<i>Vladimir V. Riabov</i>		<i>G. I. Papadimitriou, M. S. Obaidat, C. Papazoglou, and A.S.Pomportsis</i>	
Fiber Channel	205	Cryptography	505
<i>Jiying Zhao</i>		<i>Ari Juels</i>	
Storage Area Networks: Architectures and Protocols	217	Access Control	518
<i>Nirwan Ansari and Si Yin</i>		<i>Sabrina De Capitani di Vimercati, Sara Foresti, Stefano Paraboschi, and Pierangela Samarati</i>	
Distributed Intelligent Networks	235	Biometrics	539
<i>G. N. Prezerakos and I. S. Venieris</i>		<i>James L. Wayman</i>	
Smart Cards: Communication Protocols and Applications	251	Firewalls	553
<i>Michael Tunstall, Konstantinos Markantonakis, Damien Sauveron, and Keith Mayes</i>		<i>James E. Goldman</i>	
Fault-Tolerant Systems	269	Authentication	570
<i>Amiya Nayak</i>		<i>Patrick McDaniel</i>	
Distributed Algorithms	286	Password Authentication	581
<i>Valmir C. Barbosa</i>		<i>Jeremy L. Rasmussen</i>	
Distributed Databases	298	Physical Security Threats and Measures	596
<i>David Coquil and Harald Kosch</i>		<i>Mark Michael</i>	
Part 2: Network Planning, Control, and Management		Computer Security Incident Response Teams (CSIRTs)	632
Network Capacity Planning	315	<i>Raymond R. Panko</i>	
<i>Priscilla Oppenheimer</i>		Backup and Recovery System Requirements	639
Network Traffic Modeling	326	<i>David R. Reavis</i>	
<i>Thomas M. Chen</i>		Business Requirements of Backup Systems	650
Network Traffic Management	340	<i>Markus Klemen, Thomas Neubauer, and Edgar R. Weippl</i>	
<i>Thomas M. Chen</i>		Evaluating Storage Media Requirements	662
Network Security Risk Assessment and Management	354	<i>David R. Reavis</i>	
<i>Dan Port, Rick Kazman, and David Klappholz</i>		Business Continuity Planning	671
Network Reliability and Fault Tolerance	372	<i>Marco Cremonini and Pierangela Samarati</i>	
<i>Matthew Liotine</i>		E-Mail and Internet Use Policies	689
Social Engineering	384	<i>Nancy J. King</i>	
<i>Benjamin Böck, Markus D. Klemen, and Edgar R. Weippl</i>		Computer Network Management	714
Intrusion-Detection Systems	403	<i>Jian Ren</i>	
<i>Peng Ning and Sushil Jajodia</i>		Part 3: Computer Network Popular Applications and Future Directions	
Network Attacks	421	E-mail and Instant Messaging	733
<i>Mohamed Hamdi and Noureddine Boudriga</i>		<i>Bhagyavati</i>	

Application Service Providers (ASPs) <i>Bandula Jayatilaka</i>	742	Mobile Commerce <i>Vijay Atluri</i>	915
Videoconferencing <i>Ketan Mayer-Patel</i>	755	Online News <i>Bruce Garrison and Marcus Messner</i>	927
Computer Conferencing: Protocols and Applications <i>William R. Gillis and Colleen Taugher</i>	768	Travel and Tourism <i>Ulrike Gretzel, Youcheng Wang, and Daniel R. Fesenmaier</i>	943
Telecommuting and Telework <i>Michael Workman</i>	777	Web-Based Training <i>Patrick J. Fahy</i>	962
Online Banking <i>Ronnie J. Phillips</i>	791	RFID (Radio-Frequency Identification) <i>Stephen A. Weis</i>	974
Digital Libraries <i>Cavan McCarthy</i>	801	Active Networking <i>Stephen F. Bush</i>	985
Computer Conferencing and Distance Learning <i>Liam Rourke and Heather Kanuka</i>	831	Applications of Biological Concepts to Designs of Computer Networks and Network Applications <i>Tatsuya Suda, Tadashi Nakano, and Keita Fujii</i>	1012
Electronic Commerce <i>Charles Steinfield</i>	843	Nanotechnology for Communication Systems <i>Syed H. Murshid and Azhar M. Khayrattee</i>	1022
Electronic Data Interchange (EDI) <i>Matthew K. McGowan</i>	860	Molecular Communication: New Paradigm for Communication among Nanoscale Biological Machines <i>Michael Moore, Akihiro Enomoto, Tatsuya Suda, Tadashi Nakano, and Yutaka Okaie</i>	1034
Electronic Payment Systems <i>Indrajit Ray</i>	869		
Internet Relay Chat (IRC) <i>James M. Hudson and Paul L. Witt</i>	889		
Online Communities <i>Lee Sproull and Manuel Arriaga</i>	898

Preface

The Handbook of Computer Networks is the first comprehensive examination of the core topics in the computer network field. *The Handbook of Computer Networks*, a 3-volume reference work, with 202 chapters, 3400+ pages, is a comprehensive coverage of the computer network field with coverage of the core topics.

The primary audience is the libraries of 2-year and 4-year colleges and universities with Computer Science, Computer Engineering, Network Engineering, Telecommunications, Data Communications, MIS, CIS, IT, IS, Data Processing, and Business departments, public and private libraries and corporate libraries throughout the world, and educators and practitioners in the networking and telecommunications fields.

The secondary audience is a variety of professionals and a diverse group of academic and professional courses for the individual volumes.

Among industries expected to become increasingly dependent upon the computer networks and telecommunications and active in understanding the many issues surrounding this important and fast-growing field are: government agencies, military, education, libraries, health, medical, law enforcement, accounting firms, law firms, justice, manufacturing, financial services, insurance, communications, transportation, aerospace, energy, biotechnology, retail, and utilities.

Each volume incorporates state-of-the-art core information and computer networks and telecommunications topics, practical applications, and coverage of the emerging issues in the computer networks field.

This definitive 3-volume *Handbook* offers coverage of both established and cutting-edge theories and developments in the computer networks and telecommunications fields. The *Handbook* contains chapters from global experts in academia and industry. The *Handbook* offers the following unique features:

1. Each chapter follows a unique format including Title and Author, Outline, Introduction, Body, Conclusion, Glossary, Cross-References, and References. This unique format assists the readers to pick and choose various sections of a chapter. It also creates consistency throughout the entire series.
2. The *Handbook* has been written by more than 270 experts and reviewed by more than 1000 academics and practitioners chosen from around the world. These diverse collections of expertise have created the most definitive coverage of established and cutting-edge theories and applications of this fast-growing field.
3. Each chapter has been rigorously peer reviewed. This review process assures the accuracy and completeness of each topic.
4. Each chapter provides extensive online and off-line references for additional reading. This will enable the readers to go further with their understanding of a given topic.
5. More than 1000 illustrations and tables throughout the series highlight complex topics and assist further understanding.
6. Each chapter provides extensive cross-references. This helps the readers to read other chapters related to a particular topic, providing a one-stop knowledge base for a given topic.
7. More than 2500 glossary items define new terms and buzzwords throughout the series, assisting in understanding of concepts and applications.
8. The *Handbook* includes a complete table of contents and index sections for easy access to various parts of the series.
9. The series emphasizes both technical as well as managerial issues. This approach provides researchers, educators, students, and practitioners with a balanced understanding and the necessary background to deal with problems related to understanding computer networks and telecommunications issues and to be able to design a sound computer and telecommunications system.
10. The series has been developed based on the current core course materials in several leading universities around the world and current practices in leading computer, telecommunications, and networking corporations. This format should appeal to a diverse group of educators and researchers in the networking and telecommunications fields.

We chose to concentrate on fields and supporting technologies that have widespread applications in academic and business worlds. To develop this *Handbook*, we carefully reviewed current academic research in the networking field in leading universities and research institutions around the world.

Computer networks and telecommunications, network security, management information systems, network design and management, computer information systems (CIS), and electronic commerce curriculums, recommended by the Association of Information Technology Professionals (AITP) and the Association for Computing Management (ACM) were carefully investigated. We also researched the current practices in the networking field carried out by leading networking and telecommunications corporations. Our work assisted us in defining the boundaries and contents of this project. Its chapters address technical as well as managerial issues in the networking and telecommunications fields.

TOPIC CATEGORIES

Based on our research, we identified nine major topic areas for the Handbook:

- Key Concepts
- Hardware, Media, and Data Transmission
- Digital and Optical Networks
- LANs, MANs, and WANs
- The Internet, Global Networks, and VoIP
- Cellular and Wireless Networks
- Distributed Networks
- Network Planning, Control, and Management
- Computer Network Popular Applications and Future Directions

Although these nine categories are interrelated, each addresses one major dimension of the computer networks and telecommunications fields. The chapters in each category are also interrelated and complementary, enabling readers to compare, contrast, and draw conclusions that might not otherwise be possible.

Though the entries have been arranged logically, the light they shed knows no bounds. The *Handbook* provides unmatched coverage of fundamental topics and issues for successful design and implementation of a computer network and telecommunications systems. Its chapters can serve as material for a wide spectrum of courses such as:

- Grid Computing
- Distributed Intelligent Networks
- Multimedia Networking
- Peer-to-Peer Networks
- Cluster Computing
- Voice over IP
- Storage Area Networks
- Network Backup and Recovery Systems
- Digital Networks
- Optical Networks
- Cellular Networks
- Wireless Networks
- Telecommunications Systems
- Computer Network Management

Successful design and implementation of a sound computer network and telecommunications systems requires a thorough knowledge of several technologies, theories, and supporting disciplines. Networking researchers and practitioners have had to consult many resources to find answers. Some of these sources concentrate on technologies and infrastructures, some on applications and implementation issues, and some on managerial concerns. This *Handbook* provides all of this relevant information in a comprehensive three-volume set with a lively format.

Each volume incorporates core networking and telecommunications topics, practical applications, and coverage of the emerging issues in the networking and telecommunications fields. Written by scholars and practitioners from around the world, the chapters fall into nine major subject areas:

Key Concepts

Chapters in this group examine a broad range of topics. Fundamental theories, concepts, technologies, and applications related to computer networks, data communications, and telecommunications are discussed. These chapters explain the OSI reference model and then discuss various types of compression techniques including data, image, video, speech, and audio compression. This part concludes with a discussion of multimedia streaming and high definition television (HDTV) as their applications are on the rise. The chapters in this part provide a solid foundation for the rest of the Handbook.

Hardware, Media, and Data Transmission

Chapters in this group concentrate on the important types of hardware used in network and telecommunications environments and then examine popular media used in data communications including wired and wireless media. The chapters in this part explain different types of modulation techniques for both digital and optical networks and conclude with coverage of various types of multiplexing techniques that are being used to improve the efficiency and effectiveness of communications media.

Digital and Optical Networks

Chapters in this group discuss important digital and optical technologies that are being used in modern communication and computer networks. Different optical switching techniques, optical devices, optical memories, SONET, and SDH networks are explained.

LANs, MANs, and WANs

This group of chapters examines major types of computer networks including local, metropolitan, and wide area networks. Popular types of operating systems used in a LAN environment are discussed, including Windows and Linux. The chapters also examine various types of switching techniques including packet, circuit, and message switching. The chapters discuss broadband network applications and technologies and conclude with a discussion of multimedia networking.

The Internet, Global Networks, and VoIP

Chapters in this group explore a broad range of topics. They review the Internet fundamentals, history, domain name systems, and Internet2. The architecture and functions of the Internet and important protocols including TCP/IP, SMTP, and IP multicast are discussed. The chapters in this group also explain the network and end-system quality of service and then discuss VoIP and its various components, protocols, and applications.

Cellular and Wireless Networks

Chapters in this group explain cellular and wireless networks. Major standards, protocols, and applications in the cellular environment are discussed. This includes a detailed coverage of GSM, GPRS, UMTS, CDMA, and TDMA. The chapters in this group explore satellite communications

principles, technologies, protocols, and applications in detail. The chapters conclude with coverage of wireless wide area networks and wireless broadband access.

Distributed Networks

The chapters in this group investigate distributed networks, their fundamentals, architectures, and applications. Grid computing, cluster computing, and peer-to-peer networks are discussed in detail. These chapters also explore storage area networks, fiber channels, and fault tolerant systems. This part concludes with a discussion of distributed algorithms and distributed databases.

Network Planning, Control, and Management

The chapters in this group discuss theories, methodologies, and technologies that enhance successful network planning, control, and management. After discussion of network capacity planning and network modeling, the chapters concentrate on the identification of threats and vulnerabilities in a network environment. The chapters then present a number of tools and technologies that if properly utilized could significantly improve the integrity of data resources and computer networks by keeping hackers and crackers at bay. This part concludes with a discussion of business continuity planning, e-mail, and Internet use policies, and computer network management.

Computer Network Popular Applications and Future Directions

Chapters in this group present several popular applications of computer networks and telecommunications systems. These applications could not have been successfully utilized without a sound computer network and telecommunications system. Some of these applications include conferencing, banking, electronic commerce, travel and tourism, and Web-based training and education. This part concludes with a discussion of future trends in computer networking including biologically inspired networking, active networks, and molecular communication.

Specialists have written the *Handbook* for experienced and not so experienced readers. It is to these contributors that I am especially grateful. This remarkable collection of scholars and practitioners have distilled their knowledge

into a fascinating and enlightening one-stop knowledge base in computer networks and telecommunications that “talks” to readers. This has been a massive effort, but one of the most rewarding experiences I have ever had. So many people have played a role that it is difficult to know where to begin.

I should like to thank the members of the editorial board for participating in the project and for their expert advice on help with the selection of topics, recommendations for authors, and reviewing the materials. Many thanks to more than 1000 reviewers who devoted their time by providing advice to me and the authors for improving the coverage, accuracy, and comprehensiveness of these materials.

I thank my senior editor Matt Holt, who initiated the idea of the *Handbook*. Through a dozen drafts and many reviews, the project got off the ground and then was managed flawlessly by Matt and his professional team. Matt and his team made many recommendations for keeping the project focused and maintaining its lively coverage.

Jessica Campilango, our editorial coordinator, assisted our authors and me during the many phases of its development. I am grateful for all her support. When it came to the production phase, the superb Wiley production team took over. Particularly I want to thank Deborah Schindlar and Miriam Palmer-Sherman, our production editors. I am grateful for all their hard work. I also want to thank Lynn Lustberg, our project manager from ICC Macmillan Inc. Her thoroughness made it easier to complete the project. I am grateful to all her efforts. I thank Kim Dayman and Christine Kim, our marketing team, for their impressive marketing campaign launched on behalf of the *Handbook*.

Last, but not least, I want to thank my wonderful wife, Nooshin, and my two children, Mohsen and Morvareed, for being so patient during this venture. They provided a pleasant environment that expedited the completion of this project. Mohsen and Morvareed assisted me in sending out thousands of e-mail messages to our authors and reviewers. Nooshin was a great help in designing and maintaining the authors’ and reviewers’ databases. Their efforts are greatly appreciated. Also, my two sisters, Azam and Akram, provided moral support throughout my life. To this family, any expression of thanks is insufficient.

Hossein Bidgoli
California State University, Bakersfield

Guide to The Handbook of Computer Networks

The Handbook of Computer Networks is a comprehensive coverage of the relatively new and very important field of computer networks and telecommunications systems. This reference work consists of three separate volumes and 202 different chapters on various aspects of this field. Each chapter in the Handbook provides a comprehensive overview of the selected topic, intended to inform a broad spectrum of readers, ranging from computer network professionals and academicians to students to the general business community.

In order that you, the reader, will derive the greatest possible benefit from *The Handbook of Computer Networks*, we have provided this Guide. It explains how the information within it can be located.

Organization

The Handbook of Computer Networks is organized to provide the maximum ease of use for its readers. All of the chapters are arranged logically in these three volumes. Individual volumes could be used independently. However, the greatest benefit is derived if all three volumes are investigated.

Table of Contents

A complete table of contents of the entire Handbook appears at the front of each volume. This list of chapter titles represents topics that have been carefully selected by the editor-in-chief, Dr. Hossein Bidgoli, and his colleagues on the Editorial Board.

Index

A Subject Index for each individual volume is located at the end of each volume. This index is the most convenient way to locate a desired topic within the Handbook. The subjects in the index are listed alphabetically and indicate the page number where information on this topic can be found.

Chapters

The author's name and affiliation are displayed at the beginning of the chapter. All chapters in the Handbook are organized according to a standard format as follow:

Title and Author

Outline

Introduction

Body

Conclusion

Glossary

Cross References

References

Outline

Each chapter begins with an outline indicating the content of the chapter to come. This outline provides a brief overview of the chapter, so that the reader can get a sense of what is contained there without having to leaf through the pages. It also serves to highlight important subtopics that will be discussed within the chapter. For example, the chapter "The Internet Fundamentals" includes sections for Information Superhighway and the World Wide Web, Domain Name Systems, Navigational Tools, Search Engines, and Directories.

The Outline is intended as an overview and thus it lists only the major headings of the chapter. In addition, second-level and third-level headings will be found within the chapter.

Introduction

The text of each chapter begins with an introductory section that defines the topic under discussion and summarizes the content of the chapter. By reading this section the readers get a general idea regarding a specific chapter.

Body

The body of each chapter discusses the items that were listed in the outline section of each chapter.

Conclusion

The conclusion section provides a summary of the materials discussed in a particular chapter. This section leaves the readers with the most important issues and concepts discussed in a particular chapter.

Glossary

The glossary contains terms that are important to an understanding of the chapter and that may be unfamiliar to the reader. Each term is defined in the context of the particular chapter in which it is used. Thus, the same term may be defined in two or more chapters with the detail of the definition varying slightly from one chapter to another. The Handbook includes approximately 2700 glossary terms. For example, the chapter "The Internet Fundamentals" includes the following glossary entries:

Extranet A secure network that uses the Internet and Web technology to connect two or more intranets of trusted business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications.

Intranet A network within the organization that uses Web technologies (TCP/IP, HTTP, FTP, SMTP, HTML, XML, and its variations) for collecting, storing, and disseminating useful information throughout the organization.

Cross References

All the chapters in the Handbook have cross references to other chapters. These appear at the end of the chapter, following the chapter text and preceding the References. The cross references indicate related chapters that can be consulted for further information on the same topic. The Handbook contains more than 2000 cross references in all. For example, the chapter “The Internet Fundamentals” has the following cross references:

Electronic Commerce, Electronic Data Interchange (EDI), Electronic Payment Systems, History of the Internet, Internet2, Internet Domain Name System, Information Retrieval on the Internet.

References

The References appears as the last element in a chapter. It lists recent secondary sources to aid the reader in locating more detailed or technical information. Review articles and research papers that are important to an understanding of the topic are also listed. The References in this Handbook are for the benefit of the reader, to provide references for further research on the given topic. Thus, they typically consist of a dozen to two dozen entries. They are not intended to represent a complete listing of all materials consulted by the author in preparing the chapter.

INTRODUCTION

What exactly is the telecommunications industry? The industry, in fact, is hard to define because technological advances cause the industry to continually redefine itself. Indeed, the only constant in the telecommunications industry is that it is always changing. So it is a somewhat dubious task to write a chapter on such a dynamic market. Nevertheless, this chapter will attempt to provide an overview that segments the industry into different markets and shows where these markets are converging or overlapping.

This chapter will look at the industry through the eyes of an economist and policy maker rather than through the eyes of a technologist. Many of the other chapters in this book will focus on various technologies used in the industry, but this chapter will concentrate on the supply and demand of telecommunications services to the mass market: the consumer and small business marketplace. Although it may seem easier to write about economics because technologies change rapidly, the economics of supply and demand change rapidly, too, as the technological possibilities expand.

The telecommunications industry has been and will continue to be in the midst of convergence for some time. *Convergence* means that industry segments that were once separate and distinct are now overlapping and merging to provide similar competing services. Because of convergence, it is hard to draw lines of separation within the industry that are clear and meaningful. For the purposes of this chapter, we will define the three industry segments as voice, video, and data. From a purely technological standpoint, one could define voice and video as just different types of data; from the consumer perspective, however, these products are different in use and access, at least currently. Within each industry segment, there are wireline and wireless technologies that deliver these products. For voice communications, we have the choice of traditional landline phones or wireless phones. Cable television (wireline or coaxial cable), broadcast, and satellite (wireless) can deliver video. Data delivery can be done by dialup, broadband technologies such as *direct subscriber line* (DSL) and cable modem (wireline), and *wireless fidelity* (WiFi) as well as by satellite and data services provided by cell phone companies (wireless).

What is causing this convergence? There are several drivers. The first and primary driver is technology,

specifically the Internet. Internet protocol was once limited to data traffic such as e-mail and Web pages, but now it is being used to provide voice services such as *voice over IP* (VoIP) and video (e.g., *Internet protocol television*, or IPTV). Voice and video (television), which were once analog, have become digitized and delivered over an IP network. This transition has not always been smooth or easy. Two problems have plagued the transport of voice and video over IP networks: latency and prioritization. Voice and video communications require the information to arrive in the same order in which it was sent and without more than a split-second delay. Without this requirement, a packet of a conversation might arrive out of order and result in a jumbled and garbled mess. Likewise, delays of a second or more are especially noticeable in voice and video communication but are mere inconveniences to traditional data traffic such as e-mail. IP networks initially had problems transporting real-time voice and video, but the problems of latency and prioritization have largely been overcome.

But how and why did this technological change take place? In the United States, much of the freedom to allow this technological change came from the Telecommunications Act of 1996 (TA96) and associated rulings by the Federal Communications Commission (FCC). The FCC chose not to regulate nascent technologies out of existence and allowed them time to develop and mature. The intent of TA96 was “to provide for a pro-competitive, deregulatory national policy framework designed to accelerate rapidly private sector deployment of advanced telecommunications and information technologies and services to all Americans by opening all telecommunications markets to competition” (Duesterberg and Gordon 1997, 2). Thus, the second cause of convergence is the legislative and regulatory restructuring that allowed the technologies to adapt and change.

Underlying both the first two reasons of technology and restructuring is the basic economic incentive to reduce costs, increase revenues, and, ultimately, maximize profits. If VoIP can provide landline voice to customers at a much cheaper price than traditional landline networks, then there is a great economic incentive to develop it. If IPTV can enhance the revenue stream and leverage the investment for “fiber to the premises” (FTTP) and “fiber to the curb” (FTTC) projects, then the economic incentives will drive development and allocate resources

to overcome technological challenges. Ultimately, it is consumer demand and willingness to pay coupled with cost-effective technological innovation that is driving convergence.

Customers seem to be driven to purchase four products: (1) landline voice, (2) high-speed Internet access, (3) TV and entertainment, and (4) wireless voice and data. These four products have become known as the “quadruple play” by companies that seek to provide all of these services to customers, sometimes as bundles. Many telecommunications companies have merged in recent years either to increase their market share or market reach within one or more of these product areas or to provide a new product that they had not already offered to customers. For example, SBC merged with AT&T, and Cingular (owned by SBC and BellSouth) bought out AT&T Wireless. Verizon then merged with MCI, and the new AT&T (SBC-AT&T) plans to merge with BellSouth. These mergers and others have resulted in an industry that is dominated by large multimarket oligopolies.

After completing these mergers, the resulting companies have become the market leaders in each of the quadruple play markets except for TV and entertainment. The new AT&T is the second-largest local landline company (it will be the largest after its proposed merger with BellSouth), the largest long-distance company, the largest wireless provider (Cingular-AT&T Wireless), and the largest provider of DSL (and a nationwide IP network from the old AT&T). Verizon is the largest local landline company, the second-largest long-distance company, the second-largest wireless provider (Verizon Wireless with 45 percent owned by Vodafone), and the second-largest provider of DSL (and a nationwide IP network from MCI's uunet). Both companies have plans to aggressively build their fiber networks to provide TV and entertainment services.

The rest of this chapter is organized as follows. First, we will explore the landline voice market with its historical segments of local and long distance. Second, the wireless voice market will be examined along with its interactions with the landline market. Third, the video and data markets will be explained along with the wireline and wireless technologies used to supply these markets. Finally, the U.S. telecommunications market will be

compared to telecommunications markets in other developed countries.

LANDLINE VOICE MARKET

Landline voice is the oldest of the telecommunications markets discussed here; historically, it was the entire telecommunications industry. Before 1970, the landline voice market was mostly served by AT&T with its affiliated local Bell operating companies. During the 1970s and 1980s, the FCC allowed increased competition for long-distance and customer-premises equipment that culminated in the divestiture of AT&T in 1984. The divestiture required the creation of a precise definition for local and long-distance calls. This somewhat arbitrary distinction between long-distance and local telecommunications had no real foundation in cost or demand considerations. Because the distinction was a creation of regulation, market forces have caused the two markets to merge. Convergence and corporate mergers are blurring any remaining distinctions between this historical separation. SBC, the largest local company, has recently merged with AT&T, the largest long-distance company; and Verizon, the second-largest local company, has merged with MCI, the second-largest long-distance company.

Long-Distance Voice Market

Historically, long-distance voice service was provided as a monopoly service by AT&T. During the 1960s and 1970s, the FCC allowed other companies—namely, Microwave Communications Inc. (MCI) and others—to provide long-distance services in direct competition with AT&T. This policy eventually led to the divestiture of AT&T from its local telephone subsidiaries and full-fledged competition in the long-distance industry. This movement from a regulated monopoly provision of services to competitive services from many companies would be repeated throughout different industry segments.

Long-distance rates have declined significantly since the divestiture of AT&T in 1984. Figure 1 shows the decline in rates from 1984 to 2003. In 1984, the average price of a long-distance call was almost sixty cents per

Figure 1: Average revenue per minute for interstate and international calls (in 2003 dollars), 1984–2003

Figure 2: AT&T's share of total long-distance revenues, 1984–2001

minute (in 2003 dollars), but the average price was less than ten cents per minute by 2003. Much of the decline resulted from lower costs to connect calls to local telephone networks (Taylor and Taylor 1993). AT&T's market share declined from more than 90 percent in 1984 to less than 40 percent in 2001 (see Figure 2). MCI and Sprint were the second- and third-largest providers of long distance during this time, and their market shares grew as AT&T's declined. Table 1 shows the annual market share for the long-distance market between 1984 and 2001 (the most recent year the FCC produced these statistics). By 2001, MCI's market share had grown to 23.4 percent, and Sprint's had grown to 9.3 percent.

Overall, the traditional long-distance landline voice market is in serious decline for two reasons. First, the "death of distance" (Cairncross 2001) has been caused by a shift in long-distance traffic away from the public switched telephone network (PSTN) onto private data networks and the public Internet. This shift was first led by international traffic that could avoid voice call termination charges and high regulated prices by carrying the voice traffic over data lines. Even within the United States, regulatory policies caused prices for domestic long-distance calls to be high above their marginal cost. These high margins eroded as competitive alternatives became available. The second reason for the decline of the long-distance landline voice was the high market penetration of wireless phones with significantly different pricing. In 1998, AT&T Wireless's Digital One Rate incorporated long distance into the company's wireless plan at no additional charge above that for airtime. This pricing plan was quickly adopted by other wireless firms. Under this plan, customers had monthly bundles of minutes on their wireless phone contracts that they would lose if they were not used. Thus, the effective marginal price of a long-distance call on a wireless phone was zero as long as users did not exceed their allotted minutes. Not long after this, wireless plans included free calls during nights and weekends (e.g., airtime during night and weekends did not count against customers' monthly allotments of minutes). Thus, customers shifted much of their usage away from landline long distance and onto wireless phones.

Regulation of the long-distance market also changed substantially during this time (Sappington and Weisman

Table 1: Percentage Shares of Total Toll Service Revenues for Long-Distance Carriers, 1984–2001

Year	AT&T	MCU	Sprint	All Other Long Distance Carriers
1984	90.1	4.5	2.7	2.6
1985	86.3	5.5	2.6	5.6
1986	81.9	7.6	4.3	6.3
1987	78.6	8.8	5.8	6.8
1988	74.6	10.3	7.2	8.0

1996). Even after divestiture, AT&T was regulated under *rate-of-return regulation* by the FCC; it is one of the heaviest forms of regulation because it limits both profits and prices. Because MCI and Sprint had much lower market shares, they were not regulated but still filed their rates

with the FCC. This asymmetric regulation allowed MCI and Sprint to know AT&T's rates with certainty and respond in a competitive manner. The FCC changed from rate-of-return regulation to price-cap regulation in 1989, but not until 1995 was AT&T declared nondominant and effectively deregulated.

Local Voice Market

The path taken by the local voice market has been similar to that of the long-distance market. Each local market was historically served by a monopoly local telephone company that was rate-of-return regulated by the state regulatory board. Most cities and heavily populated areas were served by subsidiaries of AT&T until divestiture in 1984. At divestiture, local telephone subsidiaries were separated from AT&T's long-distance and equipment pieces. The local telephone pieces of AT&T were broken into seven different companies called *regional Bell operating companies* (RBOCs): NYNEX, Bell Atlantic, BellSouth, Ameritech, Southwestern Bell, US West, and Pacific Telesis. These companies corresponded to different geographic regions of the country (see Figure 3). The companies did not serve all customers in their regions but only major population centers. Other local telephone companies known as *independents* (because they were independent of the Bell system), served customers in the other areas.

Local telephone companies did not face competition until much later than their long-distance counterparts. In fact, competition in the local market came about because of competition in long distance. Competition in local markets started in large urban areas where new start-up companies provided direct connections from the customer to the long-distance network and thereby bypassed the local telephone network. This competition arose because of artificially high regulated rates that the local telephone companies charged to long-distance companies to connect their networks to customers. Much of this bypass was uneconomic in the sense that it was caused by regulatory rules rather than underlying differences in

costs. The upstart companies became known as *competitive access providers* (CAPs) or *alternative local transport companies* (known as ALTs). These companies continued to expand the local telecommunications services they offered until full-fledged local competition was introduced by TA96. These upstart companies became known as *competitive local exchange carriers* (CLECs) after this legislation. The traditional local telephone companies then became known as *incumbent local exchange carriers* (ILECs). Several rules from TA96 sought to put CLECs on an equal footing with ILECs. One rule was *local number portability*. For many business and individuals, changing phone numbers when changing phone service presented a great barrier to switch carriers. Because the ILECs started with all the customers, this gave them an unfair advantage in a fully competitive marketplace. To combat that advantage, local number portability required that all phone companies allow their customers to take their phone number with them when they changed local companies (Black 2002, 99).

Rates for local telephone service did not decline as they did in the long-distance market. In fact, the recurring monthly charge for basic telephone service has increased from 1986 to 2004 as shown in Figure 4: The average monthly residential charge rose from \$17.70 in 1986 to \$24.31 in 2004 (in nominal dollars). Part of the increase in local residential rates has been a shift in recovering costs away from per-minute charges (*access charges*) charged to long-distance companies and toward per-line *subscriber line charges* (SLCs) charged to end users.

The total number of switched access lines has decreased from a high of approximately 192.5 million lines in December 2000 to approximately 175.5 million in December 2005 (FCC 2006, 5). Much of the decline has been caused by people disconnecting second lines that were used for Internet connections or teenagers. These individuals have switched to broadband connections for Internet use and substituted wireless phones for teenagers. ILECs have suffered not only from the overall decline in the size of the market but also from competition with

Figure 3: RBOC regions at AT&T's divestiture, 1984

Figure 4: Total monthly charges for local services in urban areas, 1986–2004

Figure 5: Growth in CLEC market share, 1999–2005

CLECs. CLEC market share has increased steadily from 4.3 percent in December 1999 to 17.8 percent in June 2004 (see Figure 5).

In addition to suffering from the decline in second lines, the local wireline market faces competitive threats from so-called intermodal forms of competition for primary lines to a household. Loomis and Swann (2005) have shown clear links among wireless, wireline, and broadband telecommunications. In the future, more and more households will go “wireless-only” and disconnect their wireline services. Others will shift their voice usage toward *voice over IP* (VoIP), using their broadband connections and disconnecting their traditional landline phones.

The local landline market has changed considerably because of mergers since AT&T’s 1984 divestiture. Figure 3 (RBOCs at divestiture) has changed to Figure 6 (RBOCs today). In 1997, Bell Atlantic merged with NYNEX to become the new Bell Atlantic. In 2000, the new Bell Atlantic merged with GTE, the largest independent telephone company, to become Verizon. Verizon merged with MCI in 2006. Southwestern Bell Corporation changed its name to SBC Communications in 1995 and acquired Pacific

Telesis in 1997, SNET in 1998, and Ameritech in 1999. SBC merged with AT&T in late 2005 and took on the AT&T name for the company. On March 5, 2006, the new AT&T announced plans to purchase BellSouth. US West was acquired by Qwest, a long-distance company in 2000. Thus, only AT&T, Verizon, and Qwest will remain from the eight companies formed from the 1984 divestiture of AT&T.

Long-Distance and Local Voice Market

Markets that are in decline often see industry consolidation through mergers as a means to decrease costs in order to survive in a shrinking market. The local and long-distance markets have seen much industry consolidation with the top local provider (SBC) merging with the top long-distance company (AT&T) and the second-largest local company (Verizon) merging with the second-largest long-distance company (MCI). With these mergers, the distinction between local and long distance is difficult to discern except as a regulatory artifact.

In spite of blurring lines between long distance and local services, two important regulatory and public policy decisions concern the interaction between these two

Figure 6: RBOC regions, 2006

industry segments. These decisions include universal service and intercarrier compensation.

Universal service is the public policy of having a telephone network that is available, integrated, and affordable to all Americans (Mueller 1997). Historically, long-distance calls were priced above their marginal costs in order to price local telephone service below its marginal cost. This cross-subsidization was approved by both federal and state regulators to ensure that local telephone service would be affordable to most people. The divestiture of AT&T broke the linkage between long-distance and local rates. As AT&T long distance faced more competition, policy makers feared that local rates would increase and that households would disconnect their local phone service. Local rates did increase following divestiture, but households did not disconnect their phones. Instead, households responded to their total bill in which local rates increased but long-distance rates decreased even more rapidly. As a result, the market penetration rate rose from 91.4 percent in 1984 to 93.3 percent in 1990 (Hausman and Belinfante 1993).

In addition to the cross-subsidy issue from long distance to local, TA96 added the e-rate program under the category of universal service. The e-rate program provides subsidies ranging from 20 percent to 90 percent for Internet access to schools and libraries, depending on how disadvantaged they are. The fund was capped at \$2.25 billion, and the amount of requests for funding quickly exceeded the funds available. This program fundamentally changed the understanding of universal service. Previously, only landline voice service was treated as needing support under universal service; the e-rate program now extends this same type of support to Internet access.

Another area of universal service is support for high-cost rural telephone companies. The RBOCs generally serve only densely populated areas of their states. These areas are generally cheaper to serve because of economies of scale and geographical considerations. Each area of a state that is not served by an RBOC is served by an independent telephone company. The independents serve

areas that are less densely populated, more rural, and therefore of higher cost. Because of the policy of geographic rate averaging, the high-cost rural telephone companies have needed subsidies to continue to maintain low rates. These funds have come from high access charges for long-distance calls as well as surcharges on bills of all telecommunications service providers.

Access charges are a large part of the second public policy decision concerning local and long distance services: intercarrier compensation. *Intercarrier compensation* started with access-charge plans around the time of divestiture. Because AT&T was split between its long-distance and local pieces, a mechanism of prices had to be developed to charge long-distance companies for their use of the local telephone network in order to connect a long distance call. Economists had argued that these charges should only include variable traffic-sensitive costs of completing the long-distance calls; the fixed non-traffic-sensitive costs should be paid for by end users in the form of a per-line charge (later called the *subscriber line charge*, or SLC). Because of rate shock and concerns about universal service, the SLC was not set high enough to pay for all of the non-traffic-sensitive costs; the remainder was collected through increases in access charges above the traffic-sensitive cost level. This decision ultimately led to bypassing of local networks and the rise of CAPs and CLECs as discussed earlier.

TA96 recognized that the system of access charges was flawed and needed to be overhauled. The law charged the FCC with developing a solution, and the FCC devoted the third of its trilogy of orders from TA96 to *access-charge reform*. The FCC reform plan, however, has a large failure. Instead of raising the SLC, the FCC created a brand new charge—a *presubscribed interexchange carrier charge* (PICC)—that the local companies charged to the long-distance companies based on the number of customers who had that company as their default long-distance carrier. Revenue raised from this new charge was used to lower access charges. The FCC also distinguished between primary and other lines coming into a residence and allowed the SLC and PICC to be higher for nonprimary lines. The

FCC wanted the long-distance companies to absorb the PICC charges as their per-minute access charges declined. Instead, the companies passed on the new PICC charges to consumers as a new fee and, in some cases, charged more than the PICC charge. The end result was worse than if the FCC had simply raised the SLC directly. After two years, the FCC admitted its mistake and eliminated the PICC charge and began raising the SLC.

Intercarrier compensation includes more than just access charges for long-distance service. Because TA96 formalized rules for full-blown local competition between ILECs and CLECs, intercarrier compensation has also included payments, called *reciprocal compensation*, between ILECs and CLECs for terminating local traffic between subscribers. Reciprocal compensation rates were set at a fraction of the price of access charges even though the physical act of terminating a phone call is the same whether it originates across the country or across the street. Charging different prices for the same service is referred to as *price discrimination* by economists and invites *arbitrage* (buying in the low market and selling in the high market) unless there is an easy way to prevent it. In the case of reciprocal compensation, CLECs could accept long-distance traffic from the long-distance company and pass it on to the ILEC as local traffic. The CLEC would only pay the low per-minute reciprocal compensation rate, and the long-distance company would avoid the much higher access-charge rate. This act would be even easier if the CLEC and the long-distance company were part of the same holding company. Thus, there was pressure to lower access charges and make reciprocal compensation rates higher than their marginal cost.

One byproduct of having reciprocal compensation rates higher than their marginal costs was that CLECs could make a profit from terminating local traffic. One type of customer with the highest amount of terminating traffic is the Internet service provider (ISP). ISPs with dialup access have large modem banks that allow individuals to connect to the Internet by placing local calls. If the ISP is a customer of the CLEC and the individual connecting to the Internet is a customer of the ILEC, then the ILEC must pay the CLEC per-minute reciprocal compensation for the duration of the Internet connection. In this way, some CLECs received 40 percent to 70 percent of their total revenue from reciprocal compensation from the ILECs. The FCC eventually ruled that a call to an ISP was not a local call and therefore should not be subject to reciprocal compensation rules. This ruling placed some CLECs into bankruptcy.

The rules for intercarrier compensation get even more difficult when VoIP providers and wireless carriers are added to the mix. Efforts to reform intercarrier compensation and the universal service fund in order to provide a consistent plan that addresses many of the concerns already raised have been led by coalitions of industry players and regulators. One plan, known as the Missoula Plan (named for the town in which the group met at one point), was filed with the FCC in August 2006 and will be the subject of comments and debate in the coming years. The Missoula Plan task force has worked under the auspices of the National Association of Regulatory Utility Commissioners (NARUC) and is sponsored by AT&T,

BellSouth, and Cingular, as well as by approximately one-quarter of the small rural companies. Qwest, Verizon, and most wireless providers have reserved judgment on the plan.

WIRELESS VOICE MARKET

The wireless voice segment of the telecommunications industry has been one of its fastest-growing segments. This segment started in 1985 when two cellular providers were awarded licenses in each geographic territory by the FCC. One license was given to the landline company, and the other was awarded by a combination of merit hearings and lottery. This duopoly structure did not make for a competitive environment, but the industry grew at a rapid clip because of the high demand for mobility in communications. This robust demand led to calls for the FCC to allocate more radio spectrum to wireless telephony. As a result, an additional 120 megahertz (MHz) of radio spectrum was sold by the FCC in its broadband personal communication system (PCS) auctions from December 1994 to January 1997 (compared to 50 MHz for cellular at that time). In all, 2074 licenses were awarded, and more than \$20 billion was bid.

To ensure more competition than under the former duopoly structure, the FCC imposed a spectrum cap such that no single company could have a license for more than 45 MHz in any single market. In November 2001, the FCC raised that limit to 55 MHz; in January 2003, the commission eliminated the spectrum cap altogether. The elimination has led to mergers and industry consolidation. In 2004, Cingular bought AT&T Wireless (at that time, a company independent of AT&T Long Distance); in 2005, Alltel bought Western Wireless and Sprint merged with Nextel. These mergers helped solidify the dominance of four nationwide wireless carriers—Cingular, Verizon Wireless, Sprint-Nextel, and T-Mobile—with several smaller regional carriers. The firms' market shares are shown in Table 2.

In August 2006, the FCC began an auction of an additional 90 MHz of wireless spectrum. The bidders with the largest upfront deposit include a consortium of satellite TV providers, including DirecTV and EchoStar; and a group of cable TV companies, including Comcast, Time Warner Cable, and Cox Communications. Wireless providers T-Mobile, Cingular, and Verizon Wireless have also registered at the auction to acquire additional spectrum.

Table 2: Market Share by Subscriber for the Top Four Mobile Telephone Operators

Mobile Telephone Operator	Market Share (%)
Cingular Wireless	27.1
Verizon Wireless	24.2
Sprint PCS	11.9
T-Mobile	9.6

Source: Federal Communications Commission. 2005. Tables 2 and 4.

In 2008, the FCC will auction off additional spectrum that is now occupied by local television stations.

Before the creation of these nationwide carriers, the wireless industry was served by smaller regional carriers. Because customers wanted to use their wireless phones outside of their carriers' regions, each company developed roaming agreements so its customers could utilize another company's network while in its territory. The charges for using this roaming feature were passed along to the customer. Because roaming charges were much higher than the standard home rate for calls, customers complained frequently and loudly to their carriers. The development of nationwide carriers allowed consumers to use their own companies' networks and choose pricing plans that would avoid all roaming charges.

Wireless subscribers and revenues have increased rapidly over time. Figure 7 shows the rapid increase in the number of wireless subscribers, and Figure 8 shows the increase in minutes of use over wireless networks. As of December 2003, nationwide wireless penetration was 54 percent. The average minutes used per month increased from 255 minutes in 2000 to 599 minutes in 2003. Figure 9 shows that the average total bill for wireless has

declined greatly with the slight increase in recent years because of increased usage.

The wireless industry has experienced several pricing innovations that have spurred its growth. The first innovation was AT&T's Digital One Rate, which was introduced in May 1998. This plan combined wireless airtime and long-distance charges into a single rate, effectively absorbing the long-distance surcharge for long-distance calls made on wireless phones. This pricing plan was quickly copied by the other wireless companies. As mentioned earlier, this type of pricing plan cut landline long-distance usage significantly. On the flip side, it spurred wireless growth because of the "savings" in long distance that was introduced in this plan. In January 2004, AT&T Wireless also introduced mobile-to-mobile calling whereby calls to another AT&T Wireless subscriber would be free. These free calls did not count against a customer's monthly allotment of minutes; the plan helped spur customers to get their friends and family to switch to the same carrier. Similar "in-network" plans were introduced later by many other wireless companies.

Wireless companies have also provided customers with discounted or sometimes even free phones with a one- or

Figure 7: Number of mobile wireless subscribers, 1984–2004

Figure 8: Average minutes of mobile wireless telephone use (MOU) per month, 1993–2003

Figure 9: Average monthly bill for mobile wireless telephone service, 1987–2004

two-year contract. Providing a discount for the cost of buying a phone in order to use the wireless service lessened the upfront financial burden of getting service even if the monthly charge was higher as a result. Wireless companies have also signed exclusive deals with phone manufacturers to capture consumer interest in the latest technology. One example is Cingular's exclusive limited-time contract with Motorola to sell its RAZR line of phones.

As wireless phones increasingly became a substitute for landline usage, many customers started to see their wireless phones as substitutes for their landline phones. Surveys have shown that 10 percent to 15 percent of households have “cut the cord” and gone wireless only. This percentage has been highest among younger people and new households. One problem that the wireless industry faced in this substitution was that one landline phone could serve many individuals in the household. If the household consisted of a family of four, this would mean four separate wireless plans to substitute for one landline phone. To effectively lower the price of this substitution and spur growth elsewhere, the wireless companies introduced family plans in which family members could join another family member's plan for as low as \$10 per month and share their bundled minutes. These family plans lowered the price for a household to substitute wireless phones for its landline phone.

As discussed earlier, local number portability required local landline companies to allow their customers to keep their local telephone numbers when they switched carriers. This rule applied only to landline companies, so a wireless customer who changed carriers would have to change phone number and notify all of his or her contacts of the new number. This hassle gave customers a great incentive to stay with their current providers and hindered free and equal competition in the market. In November 2003, the FCC required companies in the top one hundred markets to implement local number portability and roll it out nationwide by May 2004.

Unlike landline telecommunications, the FCC and state regulatory commissions do not regulate and never have regulated wireless firms' prices or profits. However,

the FCC does hold power over the wireless spectrum licenses that the wireless companies use and can impose rules on how the firms operate; one example is the ruling on local number portability.

As the cellular industry began, the FCC required all U.S. providers to use a single analog standard called *advanced mobile phone service* (AMPS). In the mid-1990s, the wireless providers began building second-generation (2G) networks that used digital technology. These 2G networks were better than the AMPS network because they had better signal quality and used the radio spectrum more efficiently. The FCC did not mandate a 2G standard, and two different types of standards developed. The first set of standards takes samples by time and is similar to time division multiplexing of landline networks. The time-slicing techniques include *time division multiple access* (TDMA), *global system for mobile* (GSM), and *integrated digital enhanced network* (iDEN). GSM was the standard used in Europe, and most U.S. companies that started using TDMA, like Cingular, have since switched to GSM. Nextel uses the iDEN standard. The second set of standards used complex algorithms to compress digital signals. This standard is called *code division multiple access* (CDMA), and it is used by Verizon Wireless and Sprint PCS. TDMA was proven to work on a large scale sooner and enjoyed a “first-mover” advantage. CDMA is more sophisticated and expensive but ultimately was able to use radio spectrum more efficiently than TDMA. However, once a company has chosen a standard, switching technologies becomes expensive. Third-generation wireless services (3G) have been developed in Europe and Asia. Two competing standards are available: universal mobile telephone service (UMTS) (also called WCDMA), which was mandated in Europe; and CDMA2000, which is used in parts of Asia.

Of the five nationwide mobile telephone operators, Cingular and T-Mobile use TDMA or GSM as their 2G digital technology, Sprint PCS and Verizon Wireless use CDMA, and Nextel uses iDEN. Verizon Wireless has deployed 1 × RTT technology throughout its network. Discussion of the wireless carriers upgrade plans to 3G networks will be delayed until the section on data and Internet access.

VIDEO AND CABLE TELEVISION

Before the advent of cable TV, video programming was delivered by over-the-air broadcasts. The FCC licensed television channels to broadcast over *very high frequency* (VHF) from channels 2 to 13 and *ultrahigh frequency* (UHF) for channels above 13. In a typical local market, the FCC would license three to four VHF channels and several more UHF channels. A VHF station is often affiliated with one of the major commercial television net-works: ABC, CBS, NBC, and, later, FOX. Some of these stations are owned by the network, and some are independently owned but have the right to carry the network programming in their particular markets. Although a small percentage of homes receive their video programming from over-the-air broadcasts, the local network affiliated stations are usually carried to homes over cable TV and satellite (Nuechterlein and Weiser 2005, 360).

Cable TV started as noncommercial community antenna TV and was not originally seen as a competitive threat to broadcast TV over the airwaves. However, as more and more cable-only channels became available and more and more homes were passed by cable TV, cable TV became increasingly popular. As of June 2004, 98.8 percent of homes in the United States are passed by cable TV and 61 percent of homes passed subscribed to cable TV (FCC 2005, 14). Cable TV firms use coaxial cable to deliver cable content, and their networks were traditionally one-way networks that delivered video content from the cable headend to end users. To provide cable modem service (discussed in the next section), cable firms had to upgrade their networks to become two-way networks so that users could send as well as received information.

Although local broadcast stations were being seen by fewer and fewer people over the airwaves, they were still seen by many people on their cable systems as cable TV companies retransmitted local over-the-air stations on their cable systems. At first, this seemed to “save” the local broadcast channels from a slow death as the over-the-air market shrank, but station owners soon became jealous as other content channels received payment from the cable firms for their channels while the broadcast channels were essentially free. To change this situation, the Cable Act of 1992 gave broadcasters the right to forbid retransmission without their consent. This property right gave broadcasters the ability to negotiate a fee from a cable company for retransmission of its station. The broadcaster could waive this right and require the cable TV operator to carry its station under “must carry” rules. In most cases, broadcasters did not receive high monetary compensation but were able to negotiate additional channel “slots” on a cable firm’s lineup in exchange for the right to use its local network channel.

In addition to broadcast TV, cable operators faced competition from another “wireless” provider. By the mid-1990s, *direct broadcast satellite* (DBS) providers such as DirecTV and Dish Network entered the video-delivery market. The DBS market share of the video market has increased steadily, reaching 25 percent by 2004, as shown in Table 3. Among cable TV firms, Comcast is the largest with more than 21 million customers (see Table 4). Taking the video market as a whole, Comcast has the largest market share with 23 percent, and DirecTV has a

market share of 16 percent. The top ten firms are shown in Table 5.

Within the cable TV industry, firms are organized as *multiple system operators* (MSOs). There has been significant consolidation in the cable TV industry and across the landline telecommunications industry and cable TV. In 1998, AT&T, the largest long-distance company at the time, bought TCI, then the largest cable TV operator. Then, in 1999, AT&T bought Media One, the fifth-largest cable TV operator. TCI and Media One became AT&T Broadband, which was sold in 2001 to Comcast, the second-largest MSO. It seems that the convergence between cable TV and landline voice communications took longer than AT&T anticipated, and the cable TV properties were more valuable to another MSO than they were to a long-distance landline voice company.

Prices for cable TV have risen steadily over the past several years. Figure 10 shows the average price for basic service, while Figure 11 shows the average total cable bill for customers overall. Basic cable service has risen from \$11.57 in 1997 to \$13.80 in 2004, but the average total monthly bill has almost doubled from \$24.34 in 1995 to \$45.32 in 2004.

Cable TV has been regulated and deregulated several times. Before 1984, some municipalities regulated cable TV rates in addition to awarding local franchises.

However, the Cable Act of 1984 removed cable systems from municipal rate regulation where it existed. Because of this deregulation and other causes, cable rates rose 43 percent from 1986 to 1989. This sudden rise in rates led to calls for federal rate regulation. Thus, the Cable Act of 1992 required the FCC to regulate cable TV rates. This lasted until the Telecommunications Act of 1996 removed rate regulation for all cable services except basic-tier cable service.

In addition to high prices and both the regulation and deregulation of prices, the industry has also faced controversy surrounding so-called *à la carte* pricing. *À la carte* pricing refers to a pricing scheme in which consumers would only pay for channels they wanted and would not be required to buy packages or tiers of programming. Cable TV firms have consistently claimed that such a pricing scheme would raise the costs to all consumers because programming and advertising is based on the number of subscribers and this number would be reduced under such a scheme. The FCC originally agreed with the industry's analysis but has changed its mind recently. To head off a requirement to offer *à la carte* pricing, several firms have begun to offer "family-friendly" packages to placate the most vocal advocates of *à la carte* pricing.

Cable TV providers not only face current competition from DBS but also now face future competition from

Figure 10: Average monthly rates for basic services, 1997–2004

Figure 11: Average monthly rates, 1995–2004

the RBOCs that are rolling out fiber networks to provide IPTV in addition to high-speed Internet access. IPTV is projected to offer several enhancements over traditional cable TV, including greater interactivity, easier guides and channel changing, and even more channels. RBOCs have been hindered in their efforts to roll out video services because of local franchise agreements. Cable TV companies usually have franchise agreements with local municipalities, and the RBOCs argue that it would be too expensive and onerous to negotiate city-by-city franchise agreements in order for them to provide service. They have asked Congress to issue a national franchise license for them to provide video programming nationwide and have already obtained statewide franchise authority in several states.

If one takes a larger definition of the relevant market, cable TV also faces competition from videotape and DVDs and Internet video downloads such as iTunes and video iPod. With convergence comes another emerging distribution channel for video programming: the Internet. Web sites such as YouTube, Google Video, MSN video, and Yahoo Video are increasing the amount of free and paid content for viewers. In addition, TV networks are distributing their content over their own Web sites and partnering with others to sell online versions of their TV content.

The video programming and distribution industry is also somewhat vertically integrated. Several cable TV systems own parts of many of the programming channels that they and others carry on their systems. For example, Cablevision has a 60 percent ownership of American Movie Classics, Cox owns 24.6 percent of Discovery Channel, and Time Warner completely owns HBO. TV networks are owned by larger corporations that also own video content and programming. CBS is owned by Viacom, NBC is owned by General Electric and Vivendi, ABC is owned by Disney, and FOX is owned by News Corporation. Vertical integration could make it difficult for new firms to enter in competition with the cable TV firms. The Cable Act of 1992 required cable firms to make their own programming available on reasonable terms to rivals. This requirement was renewed by the FCC in 2002.

Some cable TV firms are offering voice communications (local and long distance) over their broadband cable modem systems in direct competition with the RBOCs and the long-distance companies. Most of the firms are using VoIP to provide these services over their broadband cable-modem networks. Several cable companies have also partnered with Sprint-Nextel to offer wireless phones. Convergence is taking place as RBOCs enter the video market and cable TV firms offer voice services. Both types of firms are gearing up to provide the quadruple play of voice, video, data, and wireless.

DATA AND INTERNET ACCESS

Although there was talk of alternative “information super-highways” in the 1980s, the Internet has taken over as the data network for the consumer market. The Internet is a network of networks that use the TCP/IP protocols. The Internet evolved from ARPAnet, which was developed in the 1960s by the Department of Defense; and NSFNET, which linked universities and supercomputers in the 1980s.

Despite having these roots in government funding, the Internet was privatized on April 30, 1995. There were then five major backbone providers: uunet, ANS, SprintLink, BBN, and MCI. By 2000, uunet and ANS were brought by MCI WorldCom, BBN was part of Genuity, MCI's old network was owned by Cable and Wireless, and AT&T had created its own IP network using its own fiber and purchasing IBM's Global Network. These backbone providers had peering arrangements to exchange traffic and provide links to regional networks and ISPs.

The exponential growth of the Internet would not have occurred without the development of easy-to-use end-user applications. The first applications were e-mail systems that could exchange messages between systems. End-user e-mail interfaces became easier to use with more and more features. Netscape and its World Wide Web browser popularized the use of the Internet beyond simply e-mail, and customer demand grew rapidly. The explosive growth of Web sites and extensions of basic browser functions drove consumers to demand access to the Internet and, eventually, higher speed access.

Starting in the mid-1990s, the number of residential second lines soared, driven by demand for dialup Internet access (Cassel 1999). It was not long before the attraction of always-on connectivity, faster speeds, and declining prices spurred a switch from second lines to broadband technologies. *Broadband* is defined by the FCC as speeds 200k or faster in one direction, which is low by some standards. The current technologies that offer broadband speeds are cable modems, DSL, satellite, and WiFi. The broadband market shows the greatest evidence of convergence, with cable TV firms offering cable modem service and landline voice companies offering DSL. As shown in Figure 12, cable modems have the highest percentage market share of the broadband market with 59 percent; ADSL follows with 37.2 percent. Cable modems were first to the marketplace, but ADSL has tried to close the gap in recent years with lower pricing that has led to increased market share. Table 6 shows the number of lines served by various companies that provide cable modems, with Comcast being the largest provider. Table 7 shows the

Figure 12: Broadband technologies' market share

Table 6: Major Cable Modem Providers, Ranked by Subscribership, First Quarter 2005

Company	Number of Subscribers
Comcast	7,410,000
Time Warner	4,120,000
Cox	2,750,000
Charter	1,980,000
Adelphia	1,490,000
Cablevision	1,440,000
Total North America	21,150,000

Source: Leichtman Research Group, cited in *The digital fact book*. 2005. 7th ed.

Table 7: Major DSL Providers by Subscribership, First Quarter 2005

Company	DSL Subscribers
SBC	5,610,000
Verizon	3,940,000
BellSouth	2,350,000
Qwest	1,120,000
Sprint	550,000
Covad	550,000
Total North America	14,700,000

various companies that provide ADSL, with SBC being the largest.

Landline broadband faces increasing competition from wireless technologies. The wireless technology with the most users is WiFi, which is used in home wireless networks and coffee shops. WiFi is also used by *wireless Internet service providers* (WISPs) to provide Internet services in rural communities. WiMAX is an emerging wireless technology that promises wider ranges and faster speeds than WiFi; thus, it may be a better competitor to wireline broadband. Sprint-Nextel recently announced its intention to build a “4G” wireless broadband network using WiMAX technology.

In addition to private companies building wireless broadband networks, cities and local governments have taken the initiative to build new networks. WiFi networks are being deployed across much larger geographies such as the cities of Philadelphia and San Francisco. In these cases, city governments are taking the initiative to have the technology deployed by partnering with private firms to build and manage the networks. These cities already have wireline broadband services available to most city residents. In other cases, smaller rural municipalities

are looking to build broadband networks where private companies have not deployed any broadband technologies. Other cities have opted for a landline fiber solution similar to the Utah Telecommunication Open Infrastructure Agency (UTOPIA) project. Municipal broadband has been a politically controversial topic, with private firms looking to bar municipalities from providing broadband services out of fear that subsidies from taxpayers will provide an unequal playing field and potentially delay or stop private investment.

Another politically sensitive issue concerning the Internet has been called “net neutrality.” *Net neutrality* does not have a precise definition but usually refers to a policy that broadband providers cannot charge content providers to send information over their broadband lines to end users. This policy debate began when broadband providers such as Verizon, AT&T, and Comcast proposed charging content providers such as Google and Yahoo to send data over their lines. The providers would create “fast lanes” for high-bandwidth applications such as movie downloads or streaming video. The providers claim that this would ensure these applications have the bandwidth available when they need it and would support enhanced infrastructure. Critics claim that users will end up paying twice for access to content.

Aside from Sprint’s announcement concerning WiMAX, wireless companies are already upgrading their networks to provide wireless data that surpass minimum broadband speeds. Until the major carriers upgraded their networks, less than 2 percent of their mobile traffic was data. Their second-generation networks—using GSM, CDMA, and TDMA—yielded data speeds of 9.6 to 19.2 kilobytes per second (kbps). Recently, however, several networks have been upgrading to third-generation network technologies such as *evolution data optimized* (or *only*) (EvDO) in major cities across the United States. These third-generation networks allow broadband speeds for laptops, personal digital assistants (PDAs), and cell phones from anywhere the signal reaches. Verizon Wireless launched its CDMA2000 1 × EVDO network in late 2003 and now offers it in several major U.S. cities. Sprint began to deploy this same technology in July 2005. Cingular Wireless is planning to deploy WCDMA with *high-speed data packet access* (HSDPA) technology in many major U.S. markets. This technology will allow average download speeds of 400 kbps to 700 kbps with burst rates of up to several megabytes per second (Mbps); CDMA2000 1 × EV-DO, on the other hand, delivers average user speeds of 400 kbps to 700 kbps and allows maximum data-throughput speeds of 2.4 Mbps.

INTERNATIONAL TELECOMMUNICATIONS

Although much of this chapter has focused on the U.S. telecommunications market, similar convergence of industry markets has occurred elsewhere in the world. In some cases, the United States has been in the forefront of these changes; in other cases, notably wireless and broadband data, the United States has lagged behind. The movement of landline voice services from monopoly

to competition in both local and long distance has followed the U.S. pattern with some delay. In many cases, countries first had to transition from state-owned telecommunications monopolies to private, regulated firms. In Canada, several telephone companies were owned by provincial governments. In the United Kingdom, British Telecom was privatized in 1985. In other parts of Europe, France Telecom and Deutsche Telecom moved from state-owned telephone and telegraph monopolies to private companies. In Japan, Nippon Telephone and Telegraph Corporation started the process in 1985, but in 1996 it was restructured into a holding company with a separate long-distance division and two local telephone companies, NTT East and NTT West.

After privatization, all of these countries opened their landline markets to competition. In 1985, the United Kingdom opened entry into telecom services and Japan allowed long distance and international calling competition. Canada allowed competition in long distance in 1992 and local competition in 1997. The European Union opened all telecommunications markets to competition in 1998 (Crandall 2005).

On the wireless telecommunications front, the move toward competition took a similar but delayed path in mimicking the U.S. experience. Most of the developed countries only had one or two wireless carriers as late as 1991. Even today, many countries only have two to four wireless carriers competing. In spite of being in the forefront in wireline and wireless competition, the United States has lagged behind in its auction of 3G radio spectra and deployment of 3G services. In addition, the United States ranked tenth in broadband penetration at the end of 2003 (Organisation for Economic Co-operation and Development 2005, 129).

CONCLUSION

Having looked at each of the telecommunications industry segments separately, we clearly see that each segment faces competitive inroads by other industry segments. The landline voice market (both local and long-distance) faces competition from wireless voice and cable TV companies. Cable TV firms are facing increasing competition from DBS firms and local telephone companies using IPTV. Local voice companies, cable TV firms, and wireless firms are competing for the broadband data market. Large multimarket firms will continue to increase their market shares or market reach in each of the quadruple play markets of landline voice, high-speed Internet access, TV and entertainment, and wireless voice and data.

GLOSSARY

Advanced mobile phone service (AMPS): Wireless analog standard used in the United States.

Alternative local transport carrier (ALT): Smaller local landline company that provided bypass of the ILEC network. These companies later became known as CLECs.

Code division multiple access (CDMA): A 2G wireless standard that uses complex algorithms to compress the digital signal.

Competitive access provider (CAP): Smaller local landline company that provided bypass of the ILEC network. These companies later became known as CLECs.

Competitive local exchange carrier (CLEC): Smaller, upstart company that competes with ILECs for local landline voice customers.

Digital subscriber line (DSL): A broadband Internet access service provided by LECs.

Direct broadcast satellite (DBS): Wireless video providers such as DirecTV and Dish Network that compete with cable TV companies.

Evolution data optimized (or only) (EvDO): A third-generation wireless standard that enables broadband data speeds on wireless networks.

Federal Communications Commission (FCC): The federal agency created by the Communication Act of 1934, which regulates interstate telecommunications.

Fiber to the curb (FTTC): The use of fiber optic cable to the pedestal or neighborhood and copper or coaxial cable from that point to the home.

Fiber to the premises (FTTP): The use of fiber optic cable directly to the home that replaces copper or coaxial cable.

Global system for mobile (GSM): A 2G wireless network standard that uses time-slicing techniques.

High-speed data packet access (HSDPA): A 3G wireless data standard.

Incumbent local exchange carrier (ILEC): Traditionally regulated monopoly providers of local voice landline services.

Integrated digital enhanced network (iDEN): A 2G wireless network standard that uses time-slicing techniques.

Internet protocol television (IPTV): Delivers video (television) programming to homes using Internet protocols.

Internet service provider (ISP): Company that provides Internet access to end users.

Multiple system operators (MSO): Cable TV companies that provide video programming via many different local systems.

National Association of Regulatory Utility Commissioners (NARUC): Umbrella organization representing state and federal regulatory commissions.

Presubscribed interexchange carrier charge (PICC): New charge as a result of TA96 instituted by the FCC to lower switched access fees. Charged by local companies to long-distance companies.

Public switched telephone network (PSTN): The traditional voice network operated by ILECs and long-distance voice companies.

Regional Bell operating company (RBOC): Any of seven local telephone companies created from the divestiture of AT&T in 1984.

Second generation (2G): Wireless network standards that use digital technology, including TDMA and CDMA.

Subscriber line charge (SLC): Per-line prices charged to end users that started around the time of divestiture.

Telecommunications Act of 1996 (TA96): The most recent, wide-ranging telecommunication law; technically, a rewrite of the Communications Act of 1934.

Third generation (3G): Wireless network standards that provide faster data transmission and include UMTS and WCDMA.

Time division multiple access (TDMA): A 2G wireless network standard that uses time-slicing techniques.

Universal mobile telephone service (UMTS): A 3G wireless standard also known as WCDMA.

Voice over Internet protocol (VoIP): Using Internet protocols to transmit voice conversations over data networks.

Wireless fidelity (WiFi): The popular name given to 802.11 standards for transmitting data wirelessly.

Wireless Internet service provider (WISP): Company that provides Internet access to end users using wireless technology, usually over an unlicensed spectrum.

Worldwide interoperability for microwave access (WiMAX): A newer wireless standard that allows higher speed and longer ranges than WiFi.

INTRODUCTION

This chapter reviews principles of data communications and looks at data communications components and various types of networking systems. It discusses the role of data communications in delivering timely and relevant multimedia information for decision-making purposes. Important concepts in the data communications environment will be reviewed, including data codes, analog and digital transmission, serial and parallel transmission, transmission modes, elementary data flow, protocols, and the open system interconnection reference model. The chapter also reviews data communications applications, including electronic data interchange and electronic commerce. The chapter concludes with a discussion on the growing convergence of voice, video, and data, and it highlights the importance of data communications field in the business world. The materials presented in this chapter will be further discussed in following chapters and should provide a background for the rest of the *Handbook*.

DEFINING DATA COMMUNICATIONS

The electronic transfer of data from one location to another is called *data communications*. The efficiency and effectiveness of any *computer-based information system* (CBIS) is measured in terms of the timely delivery of relevant and accurate information. Data communications enable a CBIS to deliver information where and when it is needed.

In today's national and international organizations, data may be collected in different cities, states, and even countries. If an effective data communications system is in place, then geographic organizational distribution does not impose any problems in the collection and distribution of relevant information. Data can be collected anywhere, processed, and delivered to any location throughout the world. An effective data communications system can significantly improve the efficiency and effectiveness of a CBIS by improving the flexibility of data collection and transmission. By using a portable computer, a personal digital assistant (PDA), or a palmtop computer and a communications system, an executive can communicate with his or her office at any time and from any location.

Data communications is the fundamental basis of the growing concept of the "virtual organization." This new trend indicates that an organization is not limited to its physical boundary. Various functions can be outsourced, and the results can be delivered to the organization in a timely manner by using a data communications system. A typical virtual organization requires minimal office space. Employees telecommute, and services to customers are provided through communications systems. Data communications systems are the backbone of the growing phenomena of the information superhighway and the Internet.

As Box 1 shows, the applications of data communication systems can be seen anywhere.

Box 1: Applications of data communication systems

- airline reservation systems
- audio conferencing
- automated credit card services
- automated teller machines (ATMs)
- computer conferencing
- data, voice, video, image, and fax transmissions
- distance learning and virtual learning systems
- e-government
- electronic data interchange (EDI)
- electronic commerce (EC)
- electronic file transfer
- electronic funds transfer
- electronic mail (e-mail) and instant messaging
- electronic shopping
- groupware and group support systems
- insurance applications
- Internet and global networks
- law-enforcement applications
- online banking
- online tax returns
- stock market applications
- telecommuting
- time-sharing applications
- video conferencing

BASIC COMPONENTS OF A DATA COMMUNICATIONS SYSTEM

A typical data communications system may include the following components:

- sender and receiver devices,
- modems, and
- communications media (channels).

Sender and Receiver Devices

A sender or receiver device may include one of the following components:

- input/output device;
- smart terminal;
- intelligent terminal, workstation, or microcomputer;
- network computer; or
- other type of computer.

The input/output (I/O) device, also known as a *dumb terminal*, is used only to send or receive information; it has no processing power.

A *smart terminal*, on the other hand, is an input/output device with a limited degree of processing capability. It can perform certain processing tasks, but it is not a full-featured computer. This type of device is used on factory

floors and assembly lines for data collection and transmission to a main computer system.

An *intelligent terminal*, *workstation*, or *microcomputer* serves as both an input/output device and stand-alone system. Using this type of device, the remote site is able to perform processing tasks without the support of the main computer system.

A *network computer* (NC) is a diskless computer that runs software from and saves all data to a *server*, which is a computer that provides a particular service to the client computers on the network. NCs may become more popular in the near future and should be used extensively in place of intelligent terminals. These low-priced computers can connect a user to the Internet and other networks.

Other types of computers used as input/output device include minicomputers, mainframe computers, and supercomputers.

Modems

A *modem* (modulator-demodulator) converts digital signals to analog signals that can be transferred over an analog telephone line. *Analog signals* are continuous wave patterns and are produced naturally, such as by the human voice. They are related to a continuously variable physical property, such as voltage, pressure, or rotation. *Digital signals*, on the other hand, are distinct on or off, 0 or 1, binary electrical signals. Digital signals are encoded information in a binary system, such as 0 or 1. All computers process data in digital format. Once analog signals arrive at their destination, a second modem converts them back into digital format before they enter the receiving computer.

To establish a communications link, the two devices must be synchronized. This means that both devices must start and stop at the same point. Synchronization is achieved through protocols. *Protocols* are conventions and rules that govern a data communications system. They cover error detection, message length, speed of transmission, and so forth.

Protocols also help to ensure compatibility among different manufacturers' devices.

Communications Media

Communications media, or *channels*, connect the sender and receiver devices. Communications media can be either conducted (wired or guided), such as coaxial cable, or they can be radiated (that is, transmitted wirelessly) to receiving devices such as satellite. A communications medium can be either a point-to-point or a multipoint medium. In a point-to-point system, only one device uses the medium. In a multipoint system, several devices share the same medium.

IMPORTANT EVENTS IN THE GROWTH OF DATA COMMUNICATIONS IN NORTH AMERICA

Modern communications started in 1837 when Samuel Morse constructed a working telegraph system. Table 1

Table 1: Major Data Communications Event in North America

Event	Year
Telegraph invented	1837
Western Union founded	1856
Telephone invented	1876
Bell Company founded	1877
AT&T created	1885
Telephone system regulation begins in Canada	1892
Telephone system regulation begins in United States	1910
Direct-dial long-distance service begins	1951
IBM introduces remote job entry	1954
First U.S. communications satellite sent into orbit	1958
FCC approves private microwave communication networks	1959
Satellites begin to transmit international telephone calls	1962
Packet-switching network concept proposed by the Rand Corporation	1964
Carterfone court decision permits non-Bell telephone equipment to be used	1968
ARPAnet (the foundation of the Internet) begins operation	1969
Court permits MCI to provide long-distance services	1970
Ethernet LAN specifications formulated	1972
IBM announces its systems network architecture (SNA)	1974
Microcomputer LANs introduced	1982
Breakup of AT&T into seven regional Bell operating companies	1984
Cellular phones begin service	1984
Telecommunications Act of 1996 deregulates U.S. telephone system	1996
More than 50 percent of American households own a personal computer	1998
SBC and AT&T merge	2005
Lucent and Alcatel merge	2006

highlights important events in North America that have led to today's modern communications systems.

DATA-PROCESSING CONFIGURATIONS

Over the past sixty years as the computer field has advanced, three types of data-processing configurations have emerged: centralized, decentralized, and distributed.

Centralized Data Processing

In a *centralized data-processing system*, one central location performs all data-processing tasks. In the early days of computer technology (1950s and 1960s), this type of

processing was justified because data-processing personnel were in short supply; economy of scale, both in hardware and software, could be realized; and only large organizations could afford computers.

Decentralized Data Processing

In a *decentralized data-processing system*, each user, office, department, or division has its own computer. All data-processing tasks can be implemented within each separate organizational unit. This system is certainly more responsive to the user than centralized processing. Nevertheless, decentralized systems have certain problems, including lack of coordination among organizational units, the excessive cost of having many systems, and duplication of efforts.

Distributed Data Processing

Distributed data processing (DDP) solves two of the major problems associated with the first two types of data-processing configurations: (1) lack of responsiveness in centralized processing, and (2) lack of coordination in decentralized processing. Distributed data processing has overcome these problems by maintaining centralized control while decentralizing operations.

In DDP, processing power is distributed among several locations. Databases, processing units, or input/output devices may be distributed. A good example is a newspaper publishing business in which reporters and editors are scattered around the world. Reporters gather news stories, enter them into their personal computers (PCs), edit them, and use a communications medium to forward them to the editor in charge. The reporter and the editor can be thousands of miles apart. Since the mid-1970s, with advancements in networking and microcomputers, this type of data-processing configuration has gained popularity. Some of the unique advantages of a DDP system include:

- access to unused processing power by an overused location;
- design modularity (i.e., computer power can be added or removed based on need);
- distance and location independence;
- increased compatibility with organizational growth by the addition of workstations;
- fault tolerance because of the availability of redundant resources as a security measure (i.e., if one component fails, a redundant component will take over);
- resource sharing (e.g., of expensive high quality laser printers);
- system reliability (i.e., system failure can be limited to only one site); and
- user orientation (i.e., the system is more responsive to user needs).

Some of the disadvantages of DDP include dependence on communications technology, incompatibility among equipment, and more challenging network management.

IMPORTANT CONCEPTS IN DATA COMMUNICATIONS

To better understand a data communications system and its operations, several keywords and concepts should be defined. These keywords and concepts will be further explained throughout the *Handbook*.

Data Codes

Computers and communications systems use *data codes* to represent and transfer data among various computers and network systems. Three popular types of data codes are:

- Baudot code,
- ASCII (American standard code for information interchange), and
- EBCDIC (extended binary coded decimal interchange code).

The *Baudot code* was named after French engineer Jean-Maurice-Emile Baudot. It was first used to measure the speed of telegraph transmissions. It uses five-bit patterns to represent the characters A to Z, the numbers 0 to 9, and several special characters. Using Baudot code up to thirty-two characters can be represented mathematically as $2^5 = 32$. This is not enough, however, to represent all the letters of most alphabets (uppercase and lowercase) and special characters.

To overcome this limitation, Baudot code uses *downshift* (11111) and *upshift* (11011) character code. By doing this, as many as sixty-four different characters can be defined, doubling the code's original size. This process is similar to typing using the keyboard. If the caps lock key on the keyboard is pressed, then all of the characters typed after this will be transmitted as uppercase; as soon as it is pressed again, all the characters will be transmitted as lowercase. Therefore, using Baudot, every character except for a space is either an upshift character or a downshift character. For example, 10001 represents both the letter Z and + (the plus sign). The letter Z is a downshift character, and the plus sign is an upshift character. Although Baudot code is no longer used, it illustrates how information is transmitted by a small number of bit combinations.

In the early 1960s, the American National Standards Institute developed the American Standard Code for Information Interchange, or *ASCII* (pronounced *ask-ee*). It is the most common format for text files, is used extensively in PC applications, and is ubiquitous on the Internet. In an ASCII file, each alphabetic, numeric, or special character is represented with a seven-bit binary number (a string of seven 0's or 1's). As many as 128 characters can be represented ($2^7 = 128$). UNIX and DOS-based operating systems and the majority of PC applications use ASCII for text files. Windows NT and 2000 use a newer code called *unicode*. The extended ASCII is an eight-bit code used by IBM mainframe computers that allows 256 ($2^8 = 256$) characters to be represented.

Extended binary coded decimal interchange code, or *EBCDIC* (pronounced "ehb-suh-dik") is a binary code for

alphabetic and numeric characters that IBM developed for its mainframe operating systems. It is the code for text files used in IBM's OS/390 operating system that many corporations run on IBM's S/390 servers. In an EBCDIC file, each alphabetic, numeric, and special character is represented with an eight-bit binary number (a string of eight 0's or 1's). As many as 256 characters (letters of the alphabet, numerals, and special characters) can be represented ($2^8 = 256$). Conversion programs allow different operating systems to change a file from one code to another. Table 2 illustrates selected examples of ASCII and EBCDIC.

Serial versus Parallel Transmission

In *serial transmission*, data travels in a single-file bit stream, one bit following after another. In other words, the network cable is like a one-lane road along which computers either send or receive information at any given time. In *parallel transmission*, an entire byte is transmitted at one time. Telephone lines are serial; PC printer cables are usually parallel. A network interface card takes data traveling in parallel as a group and restructures it so that it will flow through the one-bit wide path on the network cable. A network interface card is an expansion card that is required to connect a computer to a *local area network* (LAN).

Transmission Modes

Transmission modes include synchronous, asynchronous, and isochronous. In *synchronous transmission*, several characters are blocked together in parallel for transmission. At the beginning and end of each block there are empty bits, but these make up a small percentage of the total number of messages. Synchronous transmission is used to reduce overall communications costs.

In *asynchronous transmission*, each character is sent serially through a medium as an independent message. Each message is one character long, and the character is preceded by a start bit and ended with a stop bit. This type of transmission is more expensive than synchronous

Table 2: Selected Keyboard Symbols in ASCII and EBCDIC

Symbol	ASCII	EBCDIC
Space	0100000	01000000
A	1000001	11000001
B	1000010	11000010
Z	1011010	11101001
a	1100001	10000001
b	1100010	10000010
z	1111101	10101001
*	0101010	01011100
%	0100101	01101100
(0101000	01001101
0	0110000	11110000
1	0110001	11110001
9	0111001	11111001

transmission but may be more accurate. The *parity bit* is used for an error-checking procedure in which the number of 1's must always be the same—either odd or even—for each group of bits transmitted without error.

There are two types of parity: even and odd. In *even parity*, the bits are counted before they are transferred; if the total number of 1 bits is even, then the parity bit is set to 0 (the sum of the bits must be even). If the number of 1 bits is odd, then the parity bit is set to 1, making the result even. An *odd parity* bit is set to 1 if the number of 1's in a given set of bits is even (making the total number of 1's odd).

In *isochronous transmission*, the elements of both synchronous and asynchronous forms of transmission are combined. Each character is required to have both a start bit and a stop bit; however, as in synchronous data transmission, the sender and receiver are synchronized.

Data Flow

The three elementary types of data flow are simplex, full duplex, and half-duplex. In a *simplex transmission*, communication can take place in only one direction: A warehouse sends its daily transactions to the main office, for example. Radio and television signal transmissions are examples of simplex transmission.

In a *half-duplex transmission*, communication takes place in both directions, but not at the same time. This is similar to a walkie-talkie radio; only one person can talk at a time. The amount of time required for half-duplex data flow to switch between sending and receiving is called *turnaround time*. The turnaround time for different circuits varies and can be obtained from their technical specification manual.

In a *full-duplex transmission*, communication can take place in both directions at the same time.

OPEN SYSTEM INTERCONNECTION (OSI) REFERENCE MODEL

In 1979, the International Organization for Standardization (ISO) developed the *open system interconnection (OSI) reference model*. The OSI reference model is a seven-layer architecture that defines the method of transmission of data from one computer to another over a network. The model is used to control and describe the flow of data

between the physical connection to the network and the end-user application. The seven layers are as follow:

layer 7, or application layer;
layer 6, or presentation layer;
layer 5, or session layer;
layer 4, or transport layer;
layer 3, or network layer;
layer 2, or data-link layer; and
layer 1, or physical layer.

Each layer in the architecture performs a specific task. It only communicates with the layers directly above and below it; no communications are allowed directly between layers that are not directly adjacent to one another. For example, the session layer (layer 5) can only communicate with the presentation and transport layers (6 and 4, respectively).

The lowest layers—1 and 2—define the network's physical media such as network adapter cards and the cable. They also define how data bits will be transmitted over the medium. The highest layers define how user applications will access communication services. The higher the layer, the more complex its function.

Each layer provides a specific service or action that prepares the data to be transmitted over the network to another computer. The layers are separated from each other by boundaries called *interfaces*. Requests are passed from one layer, through the interface, to the next layer, and each layer builds on the services or actions provided by the layer below it.

Although the OSI model is the best known and most widely used model for describing network communications, it has been criticized for being difficult to understand and for the long time spent to have it finalized. Table 3 provides a description and the purpose of each layer in the open systems interconnection model.

The basic purpose of each layer is to provide services to the next layer. Virtual communication occurs between peer layers of the sending and receiving computers. For example, the transport layer adds information to the packet that only the transport layer on the receiving computer can interpret.

To send a packet from a source computer to a destination computer, information is sent down through each of the seven layers, picking up formatting or addressing information from each layer as it proceeds. The completed

Table 3: The Open Systems Interconnection (OSI) Model

OSI Layer	Layer Name	Focus
7	Application	Program-to-program transfer of information
6	Presentation	Text formatting and display code conversion
5	Session	Establishing, maintaining, and coordinating communication
4	Transport	Accurate delivery, service quality
3	Network	Transport routes, message handling and transfer
2	Data-link	Coding, addressing, and transmitting information
1	Physical	Hardware connections

packet, having passed through all seven layers, is then transmitted out of the network interface card, over the network cable, to the destination computer. At the destination computer, the packet is sent up through each of the seven layers in the reverse order. Each layer reads and strips away the information sent to it by its peer layer on the sending computer, then passes the packet up to the next layer. When the packet finally arrives at the application layer on the destination computer, all of the formatting and addressing information has been stripped away and the information is back in its original form.

On the sending computer, information must be passed through all of the lower layers before being transmitted over the network cable. On the receiving end, the information is passed up from the lowest to the highest layer. This means that only the physical layer is capable of communicating directly with its counterpart layer on another computer. No other layer can pass information directly to its counterpart layer on another computer.

The following sections describe the purpose of each of the seven layers of the OSI model and identify the services they provide to adjacent layers.

Layer 7: The Application Layer

The top (seventh) layer of the OSI model is the application layer. It provides services to and receives services from layer 6, the presentation layer. The application layer serves as the window that application programs use to access network services. This layer provides the services that directly support user applications such as software for file transfer, database access, and e-mail. It is application dependent and performs different tasks in different applications.

Programs, which use services of the network, reside in this layer. These programs are the ultimate consumers of network services of the lower layers. The transmission of messages used by these programs is the primary goal of the lower protocols. This is the end user's access to the network system. The application layer handles general network access, flow control, and error recovery. Its main objective is to provide a set of utilities for application programs. Examples of application layer programs are:

- AppleShare (Apple);
- file transfer protocol (FTP);
- hypertext transfer protocol (HTTP), the protocol used to access World Wide Web documents written in *hypertext markup language* (HTML); and
- X.400.

Layer 6: The Presentation Layer

The presentation layer provides services to and receives services from layers 7 and 5 (application and session, respectively). The layer formats the message and is known as the network's translator. It translates data from a format provided to it by the application layer from the sending computer into a commonly recognized format. At the destination computer, the presentation layer translates the commonly recognized format back into a format that the receiving computer's application layer can

understand. It might perform data compression, protocol conversion, and data translation.

Data encryption and character set translation such as ASCII to \leftrightarrow EBCDIC and vice versa are also performed by protocols at this layer. The redirector utility operates here and literally redirects requests for input/output operations to resources on a network server. Examples of presentation layer protocols are *hypertext transfer protocol* (HTTP) and *AppleShare file protocol* (AFP).

Layer 5: The Session Layer

The session layer provides services to and receives services from layers 6 and 4 (presentation and transport). The layer is responsible for establishing a dialogue between computers and establishes, maintains, and breaks connections or "conversations" between computers over the network. It is responsible for dialogue control by regulating which side transmits, when, and for how long. Session initiation must arrange for all of the desired and required services between session participants such as logging onto the network, transferring files, and checking security.

The session layer also provides synchronization by placing checkpoints at specific intervals in the data stream to help prevent large data losses. With the use of checkpoints, if the network fails, only the data after the last checkpoint has to be retransmitted.

Examples of session layer protocols are *transmission control protocol* (TCP) and *network basic input/output system* (NetBIOS).

Layer 4: The Transport Layer

The transport layer provides services to and receives services from layers 5 (the session layer) and 3 (the network layer). The transport layer (sometimes called the *host-to-host* or *end-to-end layer*) is responsible for providing flow control and error handling. This layer generates the receiver's address and ensures the integrity of the transmitted messages. The transport layer ensures that packets are delivered error-free, in sequence, and with no losses or duplications. This layer also provides various methods of flow control, ordering of received data, and acknowledgment of correctly received data. It is responsible for breaking large blocks of data into smaller packets, if needed, and eliminating duplicate packets.

At the destination computer, the transport layer unpacks messages, reassembles the original messages, and sends an acknowledgment of receipt. Examples of transport layer protocols include TCP and *sequenced packet exchange* (SPX) (Novell).

Layer 3: The Network Layer

The network layer provides services to and receives services from the transport and data-link layers (4 and 2). The layer is responsible for message addressing and routing as well as addressing messages and translating logical addresses and names into physical addresses. It also determines which path a packet should take based on network conditions and priority of service. The network layer also

handles tasks such as packet switching, routing, and controlling data congestion. Software at this layer accepts messages from the transport layer and ensures that the packets are directed to their proper destination. Examples of network layer protocols include TCP, the *Internet protocol* (IP), and *internetwork packet exchange* (IPX) (Novell).

Layer 2: The Data-Link Layer

The data-link layer provides services to and receives services from layers 3 and 1 (network and physical, respectively). The layer oversees the establishment and control of the communications link; its primary task is to resolve the problems caused by damaged, lost, or duplicate messages so that succeeding layers are protected against transmission errors and can assume that no errors take place. The layer also is responsible for the detection of physical errors, notification of such errors, and establishing and terminating logical links. It performs error detection, correction, and retransmission of packets if necessary.

Generally, the source computer's data-link layer waits for an acknowledgment from the destination computer's data-link layer. The destination data-link layer detects any problems with the transmission. If an acknowledgment is not received, then the source data-link layer initiates a retransmission.

When the 802 standards committee (an industry standards-setting group) decided that more detail was necessary at the data-link layer, the layer was divided into two sublayers: the *logical link control* (LLC) and the *media access control* (MAC) sublayers. The LLC is the higher of the two sublayers, and it manages data-link communication and defines the use of logical interface points called *service access points* (SAPs). The MAC sublayer provides shared access for the computers' network adapter cards to the physical layer. The MAC sublayer communicates directly with the network adapter card and is responsible for delivering error-free data between two computers on the network. It performs most of the data-link layer functions such as error detection and retransmission.

Examples of data-link layer implementation are Ethernet, token bus, and token ring.

Layer 1: The Physical Layer

The physical layer provides services to and receives services only from layer 2, the data-link layer. The physical layer is the lowest layer of the OSI model. It specifies the electrical connections between the computer and the transmission medium (such as the network cable). This layer defines the physical media through which the host communicates over the network. For example, it defines the number and function of each pin on a connector.

The layer is primarily concerned with transmitting binary data (0's and 1's), or bits, over a communication network and defines the rules by which binary data are transmitted, including the appropriate electrical or optical impulse, electrical voltages, and full duplex or half-duplex data flow and connector cable standards such as RS232, RS449, or radio frequency. This layer is also

responsible for data encoding and bit synchronization, ensuring that when a bit is transmitted as a 1, it is received as a 1 (not as a 0) at the destination computer.

The physical media can be coaxial, fiber-optic, or twisted-pair cable. The layer defines the specifics of implementing a particular transmission medium. It defines the type of cable, frequency, terminations, and so forth. The physical layer can be changed to other new technologies as they are developed without affecting the operation of upper layers, assuming that the interlayer interfaces are implemented properly.

Examples of physical layer implementation include:

- token ring;
- ArcNet;
- Ethernet:
 - 10Base-2, for thin Ethernet (coaxial) cable, commonly known as "thinnet";
 - 10Base-5, for thick Ethernet (coaxial) cable, commonly known as "thicknet";
 - 10Base-T, for unshielded twisted-pair cable, commonly known as "twisted pair";
 - 10Base-F, for fiber-optic cable, commonly known as "fiber"; and
 - other higher speed Ethernets now available, including 100BASE-FX, 100BASE-SX, and 100BASE-BX; and
- wireless:
 - broadcast radio;
 - infrared light;
 - microwave radio; and
 - spread-spectrum radio.

NETWORK TYPES

There are three major types of network systems: *local area network* (LAN), *wide area network* (WAN), and *metropolitan area network* (MAN).

A LAN system connects peripheral equipment that is in close proximity. Usually, this kind of system is limited to a certain geographical area such as a building, and one company owns it. The geographical scope of a LAN can be from a single office to a building or an entire campus. The speed of LANs varies from 10 Mbps (million bits per second) to 10 Gbps (trillion bits per second). A LAN is usually a prerequisite for an automated office in which word processing, e-mail, and electronic message distribution are integrated in one system. To establish a LAN system, careful planning and a thorough assessment of a particular organization's information needs are required.

A WAN system does not limit itself to a certain geographical area. It may span several cities, states, or even countries. Usually, several different parties own the system. The geographical scope of a WAN can be from between two or more cities to crossing international borders. The speed of a WAN depends on the speed of its individual interconnections (called *links*), and it can vary from 28,800 bps to 155 Mbps. As an example, consider a company that has its headquarters in Washington, D.C., and an office in each of thirty states. With a WAN system, all of these offices can be in continuous contact with

Table 4: LAN, WAN, and MAN Comparison

	LAN	WAN	MAN
Ownership	Usually one party	More than one party	One to several parties
Speed	100 Mbps to 10 Gbps	28.8 Kbps to 155 Mbps	34 Mbps to 155 Mbps
Scope	A building to a campus	Intercity to international	One city to several contiguous cities

the headquarters and send and receive information. An airline reservation system is another good example of a WAN. A customer can reserve an airline ticket in the United States and pick it up in Asia or Africa.

A WAN system may use many different technologies. For example, it may use different communication media (coaxial cables, satellites, and fiber optics) and terminals of different sizes and sophistication (PCs, workstations, and mainframes) and be connected to other networks.

A committee of the Institute of Electrical and Electronic Engineers has developed specifications for a public, independent, high-speed network that connects a variety of data communications systems, including LANs and WANs in metropolitan areas. This new set of standards is called a *metropolitan area network* (MAN). A MAN is designed to deliver data, video, and digital voice to all organizations within a metropolitan area. Its geographical scope usually covers a city and contiguous neighboring cities. The speed of MANs varies from 34 Mbps to 155 bps. Table 4 compares these three types of networks.

APPLICATIONS OF DATA COMMUNICATIONS

Early in this chapter we saw several applications of data communications. Volume 3 of the *Handbook* explores several applications of data communications and networking. For now, we would like to introduce two popular applications of data communications: electronic data interchange and electronic commerce. With the rapidly increasing popularity of the Internet, these applications are gaining more users.

Electronic Data Interchange

Data communications can help companies transmit data electronically over telephone lines and other communications media. These data can be directly entered into a trading partner's business application. However, data communications can only solve a part of the problem. The data are captured first and then electronically transmitted. Some manual intervention must take place here. This is where *electronic data interchange* (EDI) plays such an important role. For the purpose of this chapter, we define EDI as follows:

A computer-to-computer exchange of data in a public or industry standard format using public or private networks among trading partners. Such an exchange may include requests for quotation, purchase orders, student information, invoices, or transaction balances.

As this definition indicates, standard formats play a critical role in an EDI environment. Sending e-mail or faxes or posting through bulletin boards does not require a specific data format and standard.

Electronic data interchange was initially developed to improve response time, reduce paperwork, and eliminate potential transcription errors. EDI represents the application of computer and communications technology, supporting innovative changes in business processes. It uses a comprehensive set of standards and protocols for the exchange of business transactions in a computer-compatible format. This may cover the following applications:

- acknowledgments of business transactions,
- financial reporting,
- inquiries,
- invoices,
- order status,
- payments,
- pricing,
- purchasing,
- receiving,
- scheduling, and
- student information.

EDI is the closest option to implementing a paperless business-transaction processing system. Many businesses use EDI as a substitute for their usual method of communication where paper documents such as purchase orders, invoices, or shipping notices were physically carried from department to department, mailed or faxed from one organization to another, or manually re-entered into the computer of the recipient. Also, organizations use EDI to electronically communicate, having documents and other types of information transmitted immediately and accurately in a computer-compatible format.

EDI is different from sending e-mail or sharing files through a network (LANs, WANs, or MANs) or through an electronic bulletin board. Using these communications systems, the format of the transmitted data must be the same for the sender and receiver or successful communication will not result. When EDI is used, the format of the data does not need to be completely the same. When documents are transmitted, the translation software of EDI converts the document into an agreed-upon standard format. Once the data are received, translation software changes them into the appropriate format.

An EDI message is held within two parts known as *envelopes*. The *outside envelope* contains the interchange control information to address the message being

Table 5: Advantages and Disadvantages of EDI

Advantages	Disadvantages
Improved competitiveness Improved convenience Increased control in payments Increased customer service Increased response and access to vital information Reduced errors in ordering, shipping and receiving Reduced labor costs Reduced order lead time, resulting in reduced inventory	Different standards May incur additional costs Security issues Supplier dependence

transmitted. It can be compared to a common paper envelope that will send a letter. The *inside envelope* (the content) consists of header information, or control information such as source and destination addresses and other protocol information; and signature authentication. This inside envelope can be compared to the content of the letter that is sent in the regular paper envelope.

Table 5 summarizes EDI's advantages and disadvantages.

Electronic Commerce

Electronic commerce (EC) encompasses all the activities that a firm performs when selling and buying services and products when using computers and communications technologies. In broad terms, EC includes a host of related activities such as online shopping, sales-force automation, supply-chain management, electronic payment systems, and order management. In the last section, EDI was discussed; EC is the next step in this evolutionary progression. Technologies and applications used by EC may include (Blinch 1998; Chakravarty 1998):

- direct connectivity using LANs, MANs, and WANs;
- electronic data interchange;
- electronic mail;
- the Internet, intranets, and extranets; and
- value-added networks.

Among the products and services that customers purchase online are:

- airline tickets and travels,
- apparel and footwear,
- books and music,
- computer hardware and software, and
- flowers and gifts.

The advantages of electronic commerce include:

- doing business around the globe seven days a week, twenty-four hours a day;

- gaining additional knowledge about potential customers;
- improved customer service;
- improved relationships with the financial community;
- improved relationships with suppliers;
- increased return of capital because no or minimal inventory is needed;
- increased flexibility and ease of shopping;
- increased return on investment; and
- increased number of potential customers.

Possible capacity and throughput problems, initial investment, and security issues are among the important disadvantages of electronic commerce. However, all indications point to the elimination of these problems thereby paving the way for EC to become a common tool among all types of businesses.

CONVERGENCE OF VOICE, DATA, AND VIDEO

In the data communications field, the term *convergence* refers to the integration of voice, video, and data to provide timely and relevant multimedia information for decision-making purposes. Convergence is not just about technology. It is about services and new ways of doing business and interacting with society. In the past, separate networks were used to transmit data, voice, and video. This is changing as the technology supports such integration and as the demand for integrated services is on the rise. The integration of voice and data is almost complete in WANs.

Major carriers offer services that seamlessly integrate voice and data on the same network. The integration of voice and data has been slower in LANs mainly because of the lack of capacity and bandwidth. The integration of video with voice and data requires substantial network upgrades required by the significant bandwidth needed to carry video on the same network. However, this is changing with the increased availability of high-speed technologies such as *asynchronous transfer mode* (ATM) and *Gigabit Ethernet* (GbE) and an increased demand for new applications that require the integrated technology. Gigabit Ethernet is a LAN transmission standard that features a data-transmission rate of one billion bits per second (1 Gbps). ATM is a packet-switching service that operates at speeds of 25 to 622 Mbps.

In packet switching, small units of information known as *packets* are transmitted along the best route available between the sender and receiver. The service handles multimedia data such as text, graphics, audio, and video. The end points of the convergence market are distribution (e.g., bandwidth on demand by any medium) and content (e.g., video, audio, and data).

More and more content providers, network operators, and telecommunications and broadcasting giants, among many others, are being swept into a convergence of technologies. All the old rules about who delivers what and to whom are breaking as once-separate technologies are merging on the information superhighway. Convergence

has an impact not only on technology development and products, but also on companies and individuals. Convergence is even affecting national boundaries, with increasing numbers of companies having global access to information and even beginning to undertake worldwide project development using the Internet. Convergence is just starting; as it increases, the boundaries between products and national borders will blur even further. Convergence is possible because of a unique combination of factors that has just only begun to exist, including technological innovation, changes in market structure, and regulatory reform. Common applications of convergence include:

- e-commerce,
- entertainment (the number of television channels available will increase substantially, and movies and video on demand will become a reality),
- increased availability and affordability of video and computer conferencing, and
- consumer applications (virtual classrooms, telecommuting, virtual teams, and so forth).

The Internet is probably the most important driving force behind the growth and popularity of the convergence phenomenon. It is a vehicle for the delivery of both existing services (for example, e-mail, video, sound, and voice telephony) and completely new services. The Internet is displacing traditional computer networks and showing signs of how it may provide a platform that, over time, replaces traditional methods of trading. For example, traditional business-to-business trading on closed corporate networks is giving way to commerce on global open networks.

The Internet is also providing an alternative means of offering core telecommunications business activity (even if differences in quality still distinguish the two services) through the delivery of telephony. The Internet is also a significant platform for broadcasting services. Advances in digital technologies are helping to move the convergence of technologies forward, and when standards become available and accepted, the rate of change may speed up even further.

The lack of bandwidth is probably the most significant obstacle for the widespread applications of the convergence technologies. As new users come online, bandwidth demands increase exponentially. In addition, corporate and consumer securities and privacy are other issues that must be resolved before convergence can really take off. Security measures such as firewalls and sophisticated encryption routines are parts of the solution (Akers 1998; Bidgoli 2002; Caldwell and Foley 1998).

WHY DO MANAGERS NEED TO KNOW ABOUT DATA COMMUNICATIONS?

Data communications have become a vital and integral part of the corporate infrastructure. In fact, they have become so interwoven into the fabric of corporate activity that it has become difficult to separate the core functions of the enterprise from the data communications that enable and support that very activity.

Data communications applications can enhance the efficiency and effectiveness of decision makers by ensuring the timely delivery of relevant information. For example, data communications supports just-in-time delivery of goods, resulting in reduced inventory costs and increased competitive advantage for organizations that effectively use this technology. Large corporations such as Wal-Mart, Home Depot, J.C. Penney, Dow Chemical, UPS, and FedEx are examples of companies that have been successfully using data communications technologies in order to stay ahead of their competitors. Companies such as Ford and Intel are using virtual teams to cut across boundaries of geography, time, and organization to put together powerful teams that develop products quickly and effectively.

Data communication systems have generated opportunities for companies to use e-mail instead of the postal system and to transfer files online rather than by shipping magnetic tapes and disks. An integrated network enhances managerial control, shortens product- and service-development life cycles, and provides better information to those who need it most. Most important, an integrated network is a crucial part of an organization's international information systems infrastructure. Data communications applications directly or indirectly affect all types of organizations. The following are some of the highlights of this growing technology.

- More employees will get their education online through virtual classrooms that use data communications technologies. This will bring the latest in technology and product information right to an employee's workstation.
- Online searches over the Internet and other networks bring the latest information on products, services, and innovation right to the employee.
- The Internet and data communications will facilitate and enable lifelong learning, and knowledge will become an asset of even further importance for individuals in the future.
- Boundaries between work life and personal life will become ever more diffuse as data communications become widely available both in homes and businesses.
- Improved data communications technologies will reduce the cost and complexity of staying in touch with people.
- Customers will be able to use their televisions and PCs to access the Internet, shop, make phone calls, and conduct video and computer conferencing.

There are at least seven critical areas within the data communications field that managers should clearly understand:

1. the basics of data communications and networking;
2. the Internet, intranets, and extranets;
3. proper deployment of wired and wireless networks;
4. network security issues and measures;
5. organizational and social effects of data communications;

6. globalization issues; and
7. applications of data communications.

The *Handbook* will explain these various areas in several chapters in detail.

CONCLUSION

This chapter discussed data communications and networking principles. It introduced basic components of a data communications system, types of networks, and important events in data communications growth in North America. The chapter introduced some of the important keywords and concepts in the data communications field, including data codes, serial and parallel transmission, transmission modes, data flow, and the open system interconnection reference model. The chapter discussed electronic data interchange and electronic commerce as two of the fastest-growing applications of data communications. We concluded with a brief discussion on the convergence of data, voice, and video and a brief discussion on why managers need to know about data communications.

GLOSSARY

Communications media: Channels that connect sender and receiver devices. Communications media can be either conducted (wired or guided), such as coaxial cable; or radiated (wireless) such as satellite.

Data codes: Formats used to represent and transfer data among various computers and network systems. Popular types include Baudot, ASCII, and EBCDIC.

Data communications: The electronic transfer of data from one location to another.

Electronic commerce (EC): All of the activities a firm performs to sell and buy services and products using computers and communications technologies.

Electronic data interchange (EDI): A computer-to-computer exchange of data in a public or industry standard format using public or private networks among trading partners.

Local area network (LAN): A network that connects peripheral equipment that is in close physical proximity. Usually this kind of system is limited to a certain geographical area such as a building, and one company usually owns it.

Metropolitan area network (MAN): A network that is designed to deliver data, video, and digital voice to all organizations within a metropolitan area. The

geographical scope of a MAN usually covers a city and contiguous neighboring cities.

Modem: Abbreviation of modulator-demodulator; this device converts digital signals to analog signals and vice versa for transference over analog telephone lines.

Open system interconnection (OSI) reference model: A seven-layer architecture that defines the method of transmission of data from one computer to another over a network.

Wide area network (WAN): A type of network that is not limited to a certain geographical area. It may span several cities, states, or even countries. Usually, several different parties own it. The geographical scope of a WAN can be from intercity to international borders.

INTRODUCTION

This chapter discusses the data-link layer and the protocols associated with it. The data-link layer provides two major classes of services. First, it provides a mechanism for managing access to shared physical transmission resources. Second, it is the preliminary level of data abstraction that allows for error correction and flow control, including the retransmission of data. This addresses the issue of reliable data transfer over a network medium that is susceptible to error.

As discussed in other chapters, the *open system interconnection* (OSI) network model (ISO 1994) manages the complexity of network communications by separating protocols into a hierarchical arrangement comprising seven layers. As we move from layers 1 through 7, the associated protocols become closer to user-level abstractions and move away from the details of physical data transmission.

The data-link layer is layer 2 in the OSI model and thus exists closest to the hardware level. The OSI model is designed such that nonadjacent layers do not directly communicate with each other. Therefore, the data-link layer only has knowledge of the physical and network layers (1 and 3, respectively). Thus, the data-link layer serves as the first level of abstraction away from transmission media and toward more data-oriented functionality.

Over the history of computer networking, several data-link layer protocols have been implemented. As hardware and software needs have evolved, some of these schemes have fallen out of use. This chapter will take a look at both legacy and current protocols. However, the emphasis will be on the current implementations that the reader is more likely to encounter.

This chapter covers theoretical issues as well as practical details of existing data-link layer protocols as outlined below.

Physical Communication Architectures

The primary task of the data-link layer is to ensure that data transmissions over physical network connections

are conducted reliably. Because of the close connection to the physical layer, abstractions implemented in the data-link layer must still make use of specific aspects of the physical layer. Therefore, even at one layer above the physical layer, *network topology* plays an important role. The chapter will examine some of the details of network architecture and topology as they pertain to data-link layer implementations.

Access Control and Signaling

Many data-link implementations divide the functional concerns of shared media access and error correction between two sublayers. The *media access control* (MAC) sublayer is responsible for addressing the shared media access at the physical transmission level, while a *logical link control* (LLC) sublayer abstracts media access and multiplexing and provides for error correction. Although some access protocols do not divide the data-link layer in this fashion, the MAC and LLC sublayers are explicitly defined in Institute for Electrical and Electronics Engineers (IEEE) standards. The chapter will examine these sublayers in detail.

Specific Examples

The chapter concludes with a discussion of specific protocol implementations such as Ethernet, high-level data-link control (HDLC), fiber distributed data interface (FDDI), and token ring as examples of different schemes for addressing the data-link layer's concerns. The specifications and operations of each in their primary network environments are also discussed.

DATA TRANSFER

The physical layer provides the mechanism for transmitting data across the transmission medium. It is not concerned with the higher-level semantics of the data, but solely with the transformation of data into electromagnetic or optical signals to be expressed in a wired or wireless

medium. As such, it does not implement mechanisms to detect whether signals have been transmitted or received reliably. This is the responsibility of the next level of the OSI networking protocols: the data-link layer (also shortened in the following to just “link layer”).

The link layer provides several high-level services related to data transfer. Whereas the physical layer handles data on a bit-level basis, link layer protocols package data from the network layer into *frames* for transmission. The frames contain the metadata that provide for the transmission of the data to the correct node as well as ensure the reliability of transfer. The link layer can be designed to detect whether the data frames it receives contain errors and attempt to correct these errors. The link layer can also provide mechanisms to inspect the flow of data along the physical medium and to ensure that nodes are transmitting and receiving data at an optimal rate.

Network Topologies and Addressing

The physical layer is home to different technologies with an array of different media. The media may include copper wire, optical fibers, or specific radio frequency channels in wireless and satellite transmissions. Devices that are connected to each other across the media are called *nodes*. The nodes and their connections may be arranged in various shapes known as *network topologies*. To identify these nodes, the link layer uses a MAC addressing scheme to identify the various devices on the network. This is a distinct addressing scheme from the Internet protocol (IP) addressing that is used by the network layer. MAC addresses are unique, and most data-link implementations allow for unicast or broadcast messaging. Unicast messages are sent to a single recipient, whereas broadcast messages are sent to every node on the network. The link layer may also support multicast addressing in which a message is sent to multiple recipients defined in a group.

The topologies, the nodes, and the physical media can be described in either physical or logical terms. The *physical topology* is the arrangement of the actual wiring between or among the nodes, including any signal-extending hardware such as repeaters. The *logical topology* is a description of the network based on node connectivity (regardless of physical medium) and addressing. The data-link layer is more concerned with the logical topology of the network, although during discussion of actual link layer implementations, the choice of physical medium topology can still affect the operation of the data-link layer (e.g., the choice between a point-to-point link versus a shared bus). The following is a list of common logical topologies. There can be confusion in topology discussions, because one type of logical topology can be implemented in a different type of physical topology. Yeh and Siegmund (1980) and Stallings (1984) give good early overviews of different network topologies.

Bus

The oldest and simplest topology is the *bus*. All nodes connected to a bus share the medium, and all data are broadcast to every node regardless of individual destination. Because the data are broadcast, each node has no responsibility (unlike the ring topology reviewed next) to retransmit

frames not addressed to it. However, because the medium is shared, link utilization can decrease from frame collisions when the number of nodes increases.

Early physical implementations of the logical bus were physical buses, but today the vast majority of these layouts are implemented as stars (described below).

Ring

An early alternate topology to the bus was the *ring* topology. Nodes in a ring are connected to each other in a loop. Messages are sent from node to node (in a clockwise or counterclockwise fashion), and each node acts as a repeater (i.e., a node does not necessarily drop a message even if it is not the intended recipient). Usually, only one node is allowed to act as a transmitter at a time. This is controlled by token passing. The authorization *token* is a bit sequence that contains control information. The network has one authorization token, which is passed around from node to node. Only the node with the token may transmit.

Although the logical ring can be physically designed as a ring, star topologies with special token-passing hubs are the majority of physical designs.

Star

Although it can be more efficient than a bus, the ring architecture still passes redundant data and involves nodes that may not be the intended target. This issue is addressed by the *star* topology. In the star topology, one node called a *hub* acts as a central point for data transmission. If this hub is simply passive and retransmits all incoming frames onto the other legs of the star, then the logical star topology, while physically a star, is simply a logical bus. However, if the hub is “intelligent” and only passes frames to the correct node, then the logical topology is a true star.

The intelligent type of hub known as a *switching hub* keeps track of the unique MAC addresses of the other nodes in the network and allows for efficient point-to-point communication. It can also handle point-to-multipoint broadcasting by reserving a special address that indicates the message is intended for all nodes and then distributing messages addressed to the broadcast address to all connected nodes. Designs based around either passive or switching hubs have the significant drawback that the hub is a single point of failure. The hub must remain operational or the entire LAN is disabled.

Tree

The *tree* topology is a combination of the star and bus topologies described above. In a tree, the central hubs of multiple star networks are connected to a shared bus.

IEEE

The IEEE 802 group of protocols (IEEE 2001) split the responsibilities of the data-link layer into two sublayers. The low-level access to nodes on the network, including the addressing scheme described above, is handled by the *media access control* (MAC) layer. In addition to providing the mechanism for implementing logical topologies, the MAC sublayer implements protocols for resource sharing in which multiple nodes must use the same physical medium as a link. Above the MAC sublayer is the more abstract logical link control (LLC) sublayer. The LLC

delineates data and allows for error checking and flow control. The next two sections describe the facilities of LLC and MAC sublayers.

LOGICAL LINK CONTROL

The *logical link control* sublayer provides some higher-level services for multiplexing and demultiplexing transmissions on the MAC sublayer, as well as other optional services for detecting and retransmitting dropped frames and flow control. The following describes different services provided by the LLC (IEEE 1998).

Framing

The logical link control provides services to the network layer by creating meaningful blocks of information in the data. These data segments are called *frames*. It is the responsibility of the link layer to reliably transfer frames from point to point in the network. The link layer views transmissions in a strictly peer-to-peer fashion. It does not have a representation of the entire network but knows about nodes that can act as transmitters and receivers of frames.

The details of framing schemes vary between the numerous implemented link layer protocols. However, the basic idea is the same. Headers and trailers that contain transmission metadata are appended to the message data passed to the data-link layer from the higher OSI layers to form a frame. Frames are managed and sent to the physical layer for transmission. After frame reception, any link layer metadata are stripped from the frame before they are handed upward to the network layer. This encapsulation scheme is the hallmark of a layered network model, whether it is OSI or TCP/IP.

Error Detection and Data Recovery

Data transfer is an incompletely reliable process. The physical signals are subject to noise that can interfere with the transmission process to the extent that data become corrupted. Error detection and correction schemes attempt to compensate for the physical limitations and increase data reliability. Algorithms that attempt to counter bit errors include checksums, parity checks, longitudinal redundancy checks, and cyclic redundancy checks. Once errors are found, fixes include retransmitting and error-correcting codes. Kurose and Ross (2005) is one of several texts that supply overviews of the different algorithms.

Checksum

A simple form of redundancy checking is to treat the message data as a series of one-byte integers and then appending the sum of the integers modulo 255 as a check value. The receiver recomputes the checksum on the data it receives. If the checksum does not match, then the data are marked as corrupt. Of course, because different byte combinations may add to the same value, checksumming is not perfect and can allow errors to pass. The term *checksum* is also commonly used in a generic fashion to describe the other types of checking algorithms.

Parity Checking

One of the simplest forms of error detection is called *parity checking*. A single check bit is added to the message data before transmission. The value of this bit represents whether the number of bits with a value of 1 in the message data is odd or even. On reception, the receiver checks the data to see if the parity of the received data matches the reported parity.

Parity checking is not a robust method for error detection because the errors introduced by noise often occurs in bursts. Several bits may be changed simultaneously; this would create an error undetectable by the receiver by inspecting the check bit. Any even number of errors would produce a valid checksum and not detect the corrupt data. For example, the original sent pattern 10111011 (with an even parity of 1) corrupted to 10111000 would be received as correct because it would have the same parity value.

Longitudinal Redundancy Checking

The *longitudinal redundancy checking* (LRC) method improves on the parity checking scheme by examining the reliability across multiple bytes of the frame. LRC works by adding an additional block of check bits after several bytes of data. By treating the entire block as a two-dimensional array, parity can be checked for each row and column in the array. It is still subject to burst error, but it requires a greater number of errors and in certain patterns to generate a valid checksum for corrupt data.

Cyclic Redundancy Check

Cyclic redundancy check (CRC) is another kind of checksum algorithm that generates the check values by viewing the data bits as the coefficient of a polynomial. The data polynomial (after multiplying by x^n , where n is the degree of the CRC polynomial) is divided by a generator polynomial, and the remainder (with no carry) is used as the check value. CRC makes use of the mathematical properties of polynomials limited to binary coefficients to form what amounts to a hash code that should identify data reliably. CRC checksums do have a possibility of colliding (different bit values producing the same checksum), but with modern CRCs this is usually not a concern.

Common CRCs (and hence polynomial lengths) include CRC-16 and CRC-32 (16 and 32 represent the checksum's bit length). CRCs, especially with the larger polynomials, are quite robust to bit errors, including burst errors. Because CRCs are widely used, optimization of the implemented algorithms is important (Stone, Greenwald, Partridge, and Hughes 1998).

Forward Error-Correcting Codes

In addition to error detection, check bits can also be used for error correction. Some error correcting codes, such as Reed-Solomon, use the polynomial interpretation of the data (see the section on CRC coding above) to reconstruct corrupted data by sending an oversampled representation of the same polynomial. Thus, even if some data are lost or corrupted, the original can be determined and reconstructed. Unlike Reed-Solomon, which computes

on blocks of data, another popular type of error-correcting code—*forward error correcting*—operates on the bit stream. Other correction codes, such as Hamming codes, use multiple check bits, so if data bits are changed, the check pattern will change in a manner that identifies the position of the altered bit.

Retransmission

Error correcting codes' primary drawback is the increase in size of the transmitted frame. If bandwidth is limited, it is often more efficient and convenient to signal the sending node to retransmit the frame if the receiving node determines the data were corrupted in transit. The sender may wait for a specific signal from the receiver that indicates the need for retransmission. Conversely, the sender may resend if it does not receive an acknowledgment from the receiver after a certain amount of time. *Automatic requests for retransmission* (ARQs) are part of flow control discussed in the next section.

Flow Control

Flow controls are various mechanisms to ensure that data are not transmitted faster than the receiver can handle. Two common schemes are *blocking* and *sliding window* (Tanenbaum 1981). However, a data-link implementation may eschew any flow control and assume that a higher layer is taking the responsibility of flow control.

Blocking

Blocking protocols control data flow by implementing a turn-based system. In the simplest form of blocking, the sender sends a packet and waits for an *acknowledgement* (ack) signal sent back from the receiving node. Because only one packet is sent between each ack, a blocking scheme is highly inefficient.

Sliding Window

In the sliding window scheme for flow control, the receiving node maintains a buffer for received packets that may be larger than the packet size. This allows the transmitter to send multiple packets to the receiving node without waiting for an ack signal. The receiver (which sets the initial window size) transmits the window size; as the buffer fills, this transmitted size shrinks. If the size reaches zero, the transmitter will stop sending packets, but as the size increases, the sender may increase the number of packets it sends between ack signals. If the window size is sufficient, then packet transmission is essentially continuous, thus maximizing the throughput.

Automatic Retransmission Requests

Automatic retransmission requests (ARQs) occur when the receiver detects an error indicating that a frame is lost or corrupted. If a frame is lost, then it may not send an ack for a time period that exceeds the sender's predetermined time-out. The sender then retransmits the packet. The receiver may report a corrupted frame by sending a *nack* signal (not acknowledged message) back to the sender. In the sliding window scheme described above, the nack

may contain frame sequence information that indicates which of multiple packets need to be resent. In the so-called go-back-*n* schemes for ARQ, the sender retransmits the corrupted frame and all the frames that followed. In another approach to ARQ, known as *selective reject*, only the corrupted frame is retransmitted.

MEDIA ACCESS CONTROL

The media access control (MAC) sublayer is closer to the hardware than the LLC. It is responsible for using the physical layer for controlling access to the physical transmission medium, and it determines who has the right to transmit on a shared medium at any one time.

MAC Addresses

The MAC sublayer is also the assignment point of the link layer addressing. MAC addresses are used to deliver link layer frames to the different hosts on the link.

MAC addresses can be universally or locally administered. Universally administered addresses are assigned to each link layer device by the manufacturer. Part of the MAC address is the *organizationally unique identifier* (OUI) that is unique to each manufacturer. The rest of the address, known as the *extension identifier*, is arbitrarily determined by the manufacturer (as long as each is unique), usually using a one-up numbering with possible groupings across different models. A single manufacturer can register and pay for multiple OUIs, and these assignments are made open to the public.

Locally administered addresses are determined by the local system administrator and override the universally assigned address. To determine whether a given MAC address is local or universal, the second least-significant bit of the most significant byte can be analyzed. If it has the value of 1, then the address is administered locally; otherwise, it is administered universally.

MAC-48 was the first IEEE MAC address and was specified in the Ethernet protocol. It was named so because of its forty-eight-bit address space. The OUI is contained in the first three bytes of MAC-48, leaving twenty-four bits of addressing for the manufacturer to assign. MAC-48 technically designates link layer addresses for network hardware; the term *EUI-48* (trademarked by the IEEE) designates any other hardware and software. MAC-48 and EUI-48 are assigned from the same numbering space. Example protocols originally using MAC-48 include FDDI, ATM, and most of the IEEE 802 networks (Ethernet, Wi-Fi, Bluetooth, and token ring).

Although it will still be a while before the EUI-48 address space is exhausted, for future growth the IEEE defined EUI-64 (IEEE 2006). This sixty-four-bit address has a twenty-four-bit OUI and forty bits reserved for manufacturer assignment. This gives each OUI more than one trillion unique address assignments. The IEEE stated that each manufacturer who requests an OUI will not be able to request a second one until it has exhausted more than 90 percent of the original address space. IEEE 1394 (Firewire) is the best known protocol to use EUI-64 addresses.

An EUI-48 address can be encapsulated in an EUI-64 address for compatibility purposes. To encapsulate, a special label with hex value of FFFE is added between the OUI and extension identifier. The actual extension identifier is not changed.

MULTI-ACCESS LINK CONTROL

In many networking situations, several nodes must share the same physical transmission media. For example, in a wired LAN, several computers may need to transmit along the same wire. In wireless transmissions, some nodes need to use the same transmission channel. The link layer protocol has the responsibility to ensure that all the users of a shared resource successfully complete their transmissions. Various protocols for multi-access channel control have been developed. They can be roughly divided into the classes described next. Each has its advantages and disadvantages.

Fixed Assignment

One means of sharing the transmission resource is to assign each node a fixed slot on the resource for its use. The slots are assigned using various aspects of the signal such as frequency or timing. Most research on resource sharing concerns satellite systems and links (Elbert 1999).

Time Division Multiple Access

In the *time division multiple access* (TDMA) scheme, a single frequency can be shared by multiple users by defining and assigning time slices in which each user has the exclusive right to use the frequency. The users alternate in rapid succession, transmitting only within their allotted segment of time. With many users, this scheme requires precise and complex synchronization: If the timing is incorrect, then a user's data may drift into another's time slot. The pulsed nature of the transmissions can also create radio frequency interference as a side effect.

Frequency Division Multiple Access

The *frequency division multiple access* (FDMA) scheme allows multiple transmitters to share a single carrier frequency by subdividing it into frequency subchannels, each modulating the carrier around a slightly different range of frequencies. Each transmitter is assigned a different subchannel. Because the transmitters are all modulating the same carrier, the multiple messages are carried as a single signal along the medium. However, there is some wasted space because of needed *guard* space between each subchannel. The guard space is a gap to prevent interference between subchannels. The size of the guard space depends on many factors, including signal strength and frequency of transmission.

Spread Spectrum

The schemes above are mechanisms for sending several messages along a single frequency channel. Spread-spectrum mechanisms take the opposite approach and split a message across a frequency spectrum. In *frequency hopping spread spectrum* (FHSS), the data are segmented and each segment is transmitted over a different frequency pattern determined by a pseudorandom

process. A matched pseudorandom process is applied at the receiving end to track the varying frequencies necessary to reconstruct the message. Because numerous messages are being spread at random across a broad band, the bandwidth is used efficiently. A single message is not confined to a single frequency, so it is robust against the catastrophic interference effects that occur when different signals are transmitted along two spectrally adjacent frequencies.

Code Division Multiple Access

Code division multiple access (CDMA) splits the message across frequencies and encodes each frequency with orthogonal codes (e.g., Walsh codes).

Random Access

Fixed assignment is stable but can be inefficient (especially when there are few nodes transmitting) or too centralized. Another scheme for shared access tries to maximize the usage of bandwidth by allowing any resource to transmit at any time. Of course, this can lead to collisions, but it also can simplify the network architecture.

ALOHA

The *ALOHA network* (ALOHAnet) was implemented at the University of Hawaii in 1970. It is considered a seminal prototype in computer networking. Concepts developed for ALOHA are still in use today on LANs and other networks that need to efficiently share physical resources. Instead of assigning a fixed slot in time or frequency to a node as discussed in the previous section, ALOHA introduced the concept of *packets* by which messages would be sent in small segments at intervals that allow each node the chance to transmit a packet when an opening occurs. Because the nodes are transmitting asynchronously, two nodes may attempt to transmit at the same time, resulting in a collision in which data from both packets would be lost or corrupted. ALOHA dealt with collisions by retransmitting lost packets after a random time-out period. The random time-out at each node usually prevented a repeat collision when the failed senders tried to retransmit (Abramson 1970).

Carrier Sense Multiple Access

The random access scheme developed on ALOHAnet has evolved into a variety of *carrier sense multiple access* (CSMA) protocols. "Carrier sense" means a node first listens on the network for the presence of a carrier, indicating a message is being sent. If no carrier is detected, then the node begins transmission (Kleinrock and Tobagi 1975). Collisions may still occur, and they are handled differently by assorted CSMA protocol variants. The mechanism used by the Ethernet is known as *CSMA with collision detection* (CSMA/CD). If a node begins to send and the current on the network exceeds an expected threshold, then it registers as a collision. The node immediately stops sending data and instead sends a signal to indicate a collision has occurred. The lost data can be retransmitted when the link is clear (Metcalfe and Boggs 1976).

DATA-LINK PROTOCOL IMPLEMENTATIONS

Many link layer protocol implementations have been specified and employed throughout the years of networking one computer to another. This section delves into more details for some of the more popular protocols: HDLC, token ring, FDDI, and Ethernet. However, before discussing these, a brief discussion will be given for the data-link interfaces to the network layer.

The functionality of a network adapter card's link layer is broken up between the firmware on the card and the software in the operating system. To simplify hardware production, the majority of the link layer's code is in the software drivers. Three primary device driver specifications can be used to interface with a network card: *open data-link interface* (ODI), *network driver interface specification* (NDIS), and *packet driver*. These specifications simplify interface implementation (no need for compiling individual drivers for each machine configuration) and allow multiple protocols to be bound to a single network card.

ODI was created by Novell and Apple for their Netware and Macintosh operating systems, respectively. One of the first protocol stacks written under ODI was *inter-network packet exchange/sequenced packet exchange* (IPX/SPX) (Novell 2006). NDIS was created by Microsoft and 3Com for use in Microsoft's Windows operating systems, as well as IBM's OS/2 (Microsoft Corporation 2006). The third major interface, packet driver, was written by John Romkey while at FTP Software. The major (and nontechnical) difference is that packet driver specification is open source, along with the implemented drivers (Crynwr Software 2006).

High-Level Data-Link Control

The *high-level data-link control* (HDLC) protocol was developed by the International Organization for Standardization (ISO). Originally comprising four standards (ISO 3309, 4335, 6159, and 6256), it is now currently defined in ISO 13239 (ISO 2002). The protocol roots are in IBM's *synchronous data-link control* (SDLC) protocol.

Frame

A synchronous protocol, HDLC relies on the physical layer for clocking and frame transmission and reception synchronization. HDLC links identify the beginning and ending of a frame with a special set of bits known as the *frame delimiter*. The frame delimiter, which has a hex value of 7E (01111110), is guaranteed not to be inside of the frame. If the frame data do contain this value, then they must be escaped. If there are no data to be sent, then the link may send consecutive frame delimiters to keep the channel synchronized.

On synchronous links, a process called *bit stuffing* is used to escape the frame delimiter. During transmission of the data portion of the frame, the sender simply inserts a zero after any string of five 1's. The receiver examines the next bit after receiving those five 1's. If it is a zero, then the zero is removed and the receiver knows it is still processing data; however, if it is a 1, then the receiver must

know the current byte of data is the frame delimiter. For asynchronous links, *byte stuffing* (or *control-octet transparency*) with a control byte of hex value 7D is used. This control byte is sent before any byte with a 7D or 7E value, and then the data byte has its fifth bit inverted. The receiving byte, by recognizing the control byte and reversing the inversion, can detect the difference between control bytes, frame delimiters, and data.

In addition to the frame delimiter, a basic HDLC frame has four fields: address, control, data, and frame check sequence.

The *address* is the destination address of the frame. The length can be arbitrary, but usually is zero (point-to-point links), eight, or sixteen bits. The first bit can be used to designate a unicast (0) or multicast (1) address. The *control* field is an eight- or sixteen-bit value that defines whether the frame represents user data or control (protocol independent) data. *Data* are sets of information bits from the layer above. Their lengths can be variable. The *frame check sequence* (FCS) is used to check for bit errors and is calculated over the address, control, and data fields. Being sixteen bits long, CRC-16 is a common FCS algorithm.

Token Ring

History

The token ring interface for networking was first developed at IBM during the 1970s. Subsequently, the protocol was standardized in IEEE 802.5 (IEEE 2003). It has largely been replaced by Ethernet for LAN implementations, but it is still used where redundant, reliable transmission of data is desired. Token ring networks were originally implemented on shielded twisted-pair copper wires, but newer implementations can use fiber-optic or unshielded twisted-pair cables.

Architecture

This chapter earlier discussed the topology of a token ring network. The computers in a network are connected to each other in a loop and pass a control signal known as the *token*. In IEEE 802.5 token rings, the token is an instance of command frame (described below). If a node on the network receives the token and has data to send, it appends the data to the token and converts the token into a data frame. This message continues to circulate around the ring until it reaches its intended destination. The destination computer copies the message, reports the receipt to a special segment of the frame, and then *continues* to pass it around the ring until it returns to the source. The source can inspect the segment of the frame reserved for the destination computer to determine whether the data were received successfully. If the message was received without errors, the source computer removes the message and passes the token as a control frame once again.

Frame

The token ring protocol provides for two frame types. The unmodified token or control frame consists of three one-byte fields: start delimiter, access control byte, and end delimiter.

The *start delimiter* indicates the arrival of the token at a receiving node. The *access control byte* contains

information about the token priority and a means to detect whether the token is spinning endlessly around the ring. It also contains a bit that identifies the frame as a token and not a data/command frame. The *end delimiter* marks the end of the token.

When a node adds data to the token and unsets the token bit in the access control byte, the frame now becomes a data/command frame with the following additional fields that are inserted after the access control byte: frame control byte, destination and source address, data, and frame check sequence.

The *frame control byte* indicates whether the frame is a data frame or a control frame. If a control frame is identified, then it specifies the type of control represented. The *destination address* is the six-byte MAC address of the intended recipient of the message. The *source address* is the six-byte MAC address of the message sender. *Data* contains the message data. The *frame check sequence* (FCS) field is provided for error checking.

Fiber Distributed Data Interface

History

The *fiber distributed data interface* (FDDI) is an optical networking standard for LANs. It was developed in the mid-1980s in support of distributed applications because existing LAN technology based on token ring and Ethernet protocols could not support the networking needs of high-speed workstations used in science and engineering. FDDI also addresses the concerns of mission critical applications. It was designed to provide a robust and reliable network. FDDI is standardized by various ANSI standards.

Architecture

FDDI is primarily based on a token ring network. The FDDI protocol defines a 100 Mbps token-passing, dual ring LAN using fiber-optic cable. The reliability concerns of a single failed link bringing down the entire network are addressed by using a counter-rotating dual ring architecture. Traffic on each ring flows in opposite directions. One ring is designated as the primary ring and the other as the secondary ring.

During normal operation, only the primary ring is used to carry data. If any station on the dual ring fails, a segment of the secondary ring is used in conjunction with the original ring to rearrange the topology, wrapping it into a single ring. This wrapped ring allows for uninterrupted data flow.

Attachment Points

There are several ways to connect FDDI devices to a network. FDDI defines two types of node called *stations* and *concentrators*. Each may be single-attached or dual-attached for a total of four node types.

Single-attached devices are attached to one ring (usually the primary ring) of the counter-rotating architecture. Dual-attached rings are attached to both the primary and secondary rings. Concentrators are different from stations by acting as hubs to allow other devices to attach, either as single or dual stations. Concentrators come as *dual-attachment concentrators* (DACs) or *single-attachment concentrators* (SACs).

Dual Homing

Dual homing can be used for critical devices that need extra security against ring failures. Dual-homed devices connect to two different concentrators. One concentrator is designated as the primary or active concentrator, and the other is designated as the secondary or passive device. If the active concentrator or the link it is on fails, then the passive concentrator becomes active.

Frame

The FDDI frame format is similar to the token ring format described above. It consists of eight fields: *preamble*, *start delimiter*, *end delimiter*, *destination and source address*, *data*, *frame check sequence*, and *frame status*. The FDDI frame is essentially a token ring frame (Otto and Thomas 1996).

Ethernet

History and Overview

Arguably the most successful of the link layer protocols, practically every home or office has an Ethernet technology making up its LAN. Created in the 1970s at the Xerox Corporation (Metcalfe and Boggs 1976) and after a successful Ethernet version 1 specification developed by Xerox, Intel, and Digital Equipment Corporation, the IEEE developed the 802.3 Ethernet standards (IEEE 2005). IEEE 802.3 is what most references use as a standard in discussing Ethernet, even though Ethernet version 2 frames are still popular in networks.

Ethernet is not a single protocol but a range of protocols and technologies for layers 1 (physical) and 2 (data link) of the networking stack. Table 1 shows the mapping of the Ethernet layers to the OSI network model. This chapter only briefly mentions the physical specifications of Ethernet and instead focuses on the data-link properties, including describing common frame formats.

Within the data-link layer, the Ethernet protocols are divided into two sublayers: the *MAC* and *MAC client*. If the Ethernet adapter is in a normal end host, or *data terminal equipment* (DTE), the MAC client is a LLC. The LLC provides access between the link and network layers through a well-defined interface given in IEEE 802.2 specifications. If the Ethernet adapter is instead located in *data communication equipment* (DCE), the MAC client is a *bridge entity*. Defined by IEEE 802.1, bridge entities

Table 1: Mapping of the Ethernet Data-Link and Physical Layers to the OSI Model

ISO Reference Model	Ethernet Reference Model

provide interfaces for connecting LANs regardless of protocol homogeneity.

The MAC sublayer provides access to the physical layer and defines the Ethernet frame format. Across a variety of Ethernet technologies and speeds (some with extensions to the basic frame format), the MAC sublayer is protocol specific. A primary responsibility of the MAC sublayer is the encapsulation of the data given from the higher layer (i.e., LLC) by wrapping Ethernet fields around the data and producing a valid Ethernet frame. Once a frame is constructed, the MAC must start the transmission process of the frame, as well as handle any errors arising during the transmission process.

Physical Specifications and Data Rates

The different physical specifications and implementations of Ethernet can be grouped by the bandwidth that each technology provided. The first Ethernet standards specified bandwidths of 10 Mbps. Fast Ethernet bumped the bandwidth to 100 Mbps, Gigabit Ethernet increased bandwidth to 1000 Mbps, and the recent 10-Gigabit Ethernet standard specifies a 10,000 Mbps bandwidth. Table 2 lists examples of Ethernet specifications grouped by speed along with columns for types of cabling and possible topologies.

Sharing the Medium

Ethernet shares the medium between all the users on the link by using a scheme mentioned earlier known as *carrier sense multiple access with collision detection* (CSMA/CD). This multiple-access scheme requires no centralization of host transmission, no special token frames, and no time slots. The algorithm does require the Ethernet adapter to determine when the link is free to transmit (carrier sense) and to determine when different hosts have transmitted frames concurrently (collision detection).

The CSMA/CD algorithm can be written in pseudocode as follows.

Step 1: An Ethernet frame is prepared for transmission with data from the network layer.

Step 2: If the link media is busy, then wait.

Step 3: Transmit the frame.

Step 4: Listen for colliding frames. If there is no collision, the frame has been successfully transmitted and the algorithm can restart at step 1.

Step 5: If collision detected, transmit a *jam signal*.

Step 6: Abort the entire process for the frame if the number of transmission attempts has been exceeded.

Step 7: Wait a computed back-off time before re-entering step 2.

Once the Ethernet adapter has detected a busy carrier in step 2 and has to wait, the adapter also has to wait an additional amount of time called the *interframe gap* (or *interframe spacing*) once the medium is clear. The interframe gap is a type of rest period between Ethernet frames to allow network adapters to get ready for the next frame. Gap time minimums are based on the amount of time to transmit ninety-six bits, so the interframe gap time is relative to each Ethernet technology's transmission speeds.

The *jam signal* in step 5 is a thirty-two-bit signal that makes sure all the other hosts on the link detect colliding frames. The jam signal is necessary because it is possible for not enough signal energy to be generated and transmitted back to the first transmitting host for it to detect a collision if the second sending host immediately stopped transmitting when a collision was detected.

In step 7, the back-off time is computed by an *exponential back-off* algorithm: given that the network adapter is attempting to transmit a frame that has experienced n collisions, the adapter waits $512k$ bit-times where k is chosen randomly with $0 \leq k < 2^m$ and m is the minimum of n , and the standard back-off limit of 10. With a wait time based on a power of 2 and a maximum wait time

Table 2: Ethernet Specifications

Ethernet Family	Speed	Technology	Cabling	Topology
Standard Ethernet	10 Mbps 10Base2 10Base-T 10Base-F	10Base5 Coaxial (thinnet) Twisted pair Fiber-optic	Coaxial (thicknet) Bus Star Star	Bus
Fast Ethernet	100 Mbps	100Base-TX 100Base-T4 100Base-FX 100Base-SX	Cat5 twisted pair Cat3 twisted pair Fiber-optic (laser) Fiber-optic (LED)	Star Star Star Star
Gigabit Ethernet	1000 Mbps	1000Base-T 1000Base-LX 1000Base-SX	Cat5 twisted pair Fiber-optic (laser) Fiber-optic (LED)	Star Star Star
10-gigabit Ethernet	10000 Mbps	10GBase-T 10GBase-SR 10GBase-LR 10GBase-LX4	Cat5/5e/6 twisted pair Fiber-optic (multimode) Fiber-optic (single mode) Fiber-optic (multiplexed)	Star Star Star Star

bounded by the back-off limit, the back-off algorithm is more formally noted as a *truncated binary exponential back-off*. The exponential back-off algorithm ensures two things: (1) a random wait time to make sure two colliding hosts do not retransmit at the same time and recollide and (2) a longer and longer wait time for duplicate colliding frames to reduce the amount of collisions on a busy Ethernet network.

Efficiency

Much literature has been dedicated to the analysis of the performance and efficiency of the various Ethernet technologies. Deriving a simple closed-form efficiency equation is difficult, given the number of empirical factors in an Ethernet link. Kurose and Ross (2005), citing Lam (1980) and Bertsekas and Gallagher (1991), have given an approximation of Ethernet efficiency:

$$\text{Efficiency} = \frac{1}{1 + 5(t_{\text{propagation}}/t_{\text{transmission}})}$$

The maximum time of energy from a signal propagating between the most distant adapters is $t_{\text{propagation}}$, and the time to transmit the largest Ethernet frame is $t_{\text{transmission}}$. From the above relationship, two conclusions can be formed: When propagation times rise, efficiency goes down (or becomes perfect when the time nears zero); and when the size of the Ethernet frames becomes smaller, efficiency goes down (or becomes perfect when the frame size approaches infinity).

Frame

There are seven basic Ethernet frame fields: preamble, start-of-frame delimiter, destination address, source address, type or length, data, and frame check sequence. Advanced Ethernet standards, such as Gigabit Ethernet, may extend or modify these.

The *preamble* is a seven-byte bit-synchronization pattern of alternating 0's and 1's. Following the preamble is the one-byte *start-of-frame delimiter* (10101011) that marks the beginning of a valid Ethernet frame.

After these eight bytes of synchronization and signaling, the actual Ethernet data follows, starting with the *destination address* and *source address*. Each address is six bytes and is also known as a MAC address. The destination MAC address can represent a single host address (unicast) or a group of addresses. If the first bit of the destination is a 0, then the address is an individual host, but a 1 represents a group of hosts. Furthermore, if a group of addresses is specified, the grouping can be based on all the hosts on the link (broadcast) or a logical subset of users (multicast). A multicast address is an a priori agreed-to address for the group, whereas the broadcast address bits are all set to 1's.

The next field can either be the *type* field or *length* field. The IEEE 802.3 Ethernet standard defines the two-byte field following the source address as the length field, marking the number of bytes in the data field. Other Ethernet standards' frames, most notably the Ethernet II frame (also known as the DIX frame, named from the joint work by the Digital Equipment Corporation, Intel, and Xerox) treat this field as a type field, noting the type of protocol in the network layer that generated the frame. A majority of implemented Ethernet networks use the DIX frames, and the 802.3 specification now recognizes either use of the

type or length field as valid. An Ethernet frame is limited to 1500 bytes by 802.3. If the type or length field's value is less than or equal to 1500, then the field's value represents the value of the data field. Type values are defined by field values greater than or equal to 1536 (0×600).

The *data* field follows the type or length field. The minimum length of the data field is 46 bytes, whereas the maximum length is 1500 bytes. If the data from the network layer are less than 46 bytes, then padding bytes are added to the user data. The maximum length of the data field is also known as the *maximum transmission unit* (MTU). Ethernet is such a ubiquitous protocol that modern operating systems IP stacks default to generating 1500 byte datagrams for the Ethernet frame. However, if the datagram traverses a part of the network with a smaller MTU, then it is the responsibility of the network layer (i.e., the IP layer), to split the datagram.

The final standard Ethernet field is the four-byte *frame check sequence* field. It is an error-detection field containing a thirty-two-bit cyclic redundancy check value. The CRC value is computed using the values of the data, length or type, and both address fields. Because Ethernet is defined as a connectionless and unreliable service, the responsibility for a frame with a bad CRC lies with the higher layers, and the failed CRC frames are dropped by the network card driver. The frame's data would only be retransmitted if a higher layer was using a reliable service such as TCP.

Because of the higher transmission speeds of Gigabit Ethernet, the minimum frame size was increased to 520 bytes for 1000base-T and 416 bytes for 1000Base-X implementations. To retain compatibility with the basic Ethernet frame, the possible extra padding these increased minimums bring are not added in the data field (as described above) but in an extra *extension* field. This extension field is appended to the end of the frame.

Another Gigabit Ethernet update to the original specification was the addition of a *frame burst mode*. In this mode, a host is allowed to send additional frames up to 65,536 bit times without giving up the medium. In between the "bursting" frames, the sending host fills the interframe gaps with extension bits so that the other hosts know not to attempt to transmit (Cisco Systems 2004).

Transmission Modes

The original standard transmission mode for Ethernet is half-duplex. On a single Ethernet link only one host can be transmitting data at a time. For the host to receive data, it must stop transmitting. Every Ethernet standard must work at half-duplex. Usually, performance metrics and Ethernet parameters are given assuming half-duplex transmission.

Transmission in full duplex began as an optional mode for Ethernet, but because almost every adapter supports it, has become the de facto standard. Full duplex mode is actually simpler than half-duplex mode, but it does require two point-to-point links to be established between the target Ethernet nodes. Once the two links are established, Ethernet data flows in one direction on one link and in the opposite direction on the other. This removes media contention, thus removing collisions and retransmitted frames. The original requirement to keep the interframe gap is still needed, although frame extension bits for short frames are not necessary (Cisco Systems 2004).

CONCLUSION

We hope this chapter has provided a foundation for understanding the data-link layer. Located one step above the physical layer, the layer is vital for reliable transmissions between nodes in a computer network. It is important to understand the different link layer specifications and the various implementations that exist and how they both influence and are influenced by the network topologies and physical media. Errors in engineering the data-link layer could range from slight (selecting an incorrect frame size) to severe (providing no collision detection for a busy shared bus). Such mistakes can lead to correspondingly severe and negative consequences in the overall efficiency of network communication.

GLOSSARY

Automatic retransmission request (ARQ): A strategy for error correction in which the sender retransmits a frame if an acknowledgement message is not received within a specified time period.

Data-link layer: Layer 2 of the OSI model.

Frame: Logical grouping of data to be transmitted across the network.

Frame acknowledgement signal (ack): A signal sent from the receiver to the transmitter to indicate a frame was successfully transmitted.

Logical link control (LLC): Higher-level sublayer of the data-link layer.

Logical topology: Abstract arrangement of nodes on the network independent of wiring.

Media access control (MAC): Lower-level sublayer of the data-link layer.

Nack: Frame has not successfully received signal.

Node: A device that acts as a transmitter or a receiver on the network.

Physical topology: Arrangement of the physical wiring between nodes on a network.

Token: Special control sequence that is used especially in networks with ring topologies.

INTRODUCTION

A protocol is a collection of standard conventions and rules that govern communication between entities in the same or different environments. The *Internet protocol* (IP) serves to interconnect systems in packet-switched networks. IP is the routed network layer protocol of the Internet that encapsulates upper-layer protocols (e.g., TCP and *user datagram protocol*, or UDP) packets as *datagrams* for transmission over various layer 2 technologies such as Ethernet, wireless fidelity (WiFi), and point-to-point protocol (PPP).

IP offers unreliable connectionless services and depends on transport layer protocols such as TCP and UDP to deliver error-free, duplication-free flow control and sequenced delivery of packets. To fulfill its objective—that is, transmission of datagrams end to end—the IP performs three main tasks: *addressing*, *fragmentation and reassembly*, and *packet forwarding*.

Each network interfacing card attached to end hosts or routers is identified by a unique address called an *IP address*. When a datagram is received by a system, the IP module residing on that system accesses the *header* of the datagram to obtain the destination IP address and forward the datagram toward the destination accordingly.

When datagrams are transmitted from one network to another that has a smaller *maximum transmission unit* (MTU) size, the IP performs fragmentation to enable the datagrams to fit on the underlying link layer protocols. Specific fields and flags in the IP header of a datagram provide all of the necessary information required to reassemble the fragments to re-create the original datagram. This reassembly process is performed at the ultimate destination of the datagram.

The selection of the next hop through which a datagram is forwarded from the source host to the destination host is called *datagram forwarding*. The IP module

determines the next hop by consulting the routing table and makes its forwarding decision accordingly.

IP is a *routed network layer protocol*. This means that routers can forward IP packets through an internetwork toward their intended destination. On the other hand, *routing protocols* maintain the routing tables so that they reflect the actual topology of the network. Routing protocols are categorized into *interior gateway protocols* (IGPs) and *exterior gateway protocols* (EGPs).

EGPs route datagrams between *autonomous systems* (i.e., multi-internetwork environments), while IGPs route datagrams within a single routing domain or an autonomous system (a single administrative entity). Examples of IGPs include: *routing information protocol* (RIP and RIPv2), *interior gateway routing protocol* (IGRP), *enhanced interior gateway routing protocol* (EIGRP), *open shortest path first* (OSPF), and *intermediate system to intermediate system* (IS-IS). An example of an EGP is the *border gateway protocol* (BGP).

An IP datagram consists of a header and data (i.e., *payload*). Figure 1 shows the structure of an IP datagram header. Explanations of some of the important fields follow.

- *Type of service*: This set of abstract unified parameters indicates a certain service request.
- *Precedence, delay, throughput, and reliability*: These form the whole set of the abstract parameters and define the handling mechanism of datagram transmissions through the internetwork by mapping them into real service types.
- *Time to live*: A time limit is assigned by the sending host for the datagram to be delivered to its destination. If the time to live for a datagram reaches zero before it reaches the destination, the datagram will be discarded. This mechanism limits the upper-bound lifetime of

datagrams, thus suppressing undesired loops, discarding undelivered datagrams, and sometimes preventing old datagram duplications.

- **Options:** These provide predefined optional routing methods. It is up to the sender to choose one or not. Nevertheless, Internet modules of each node should be able to interpret it and react accordingly. Option definitions include *security*, *loose secure routing*, *strict secure routing*, *record route*, *stream identifier*, and *Internet timestamp*.
- **Header checksum:** This error-detection mechanism enforces the correctness of a datagram's header, ensuring that the processing of the datagram is done accurately during the whole transmission process. When an error occurs, it will be reflected in the *checksum*.

Working with the IP, the *Internet control message protocol* (ICMP) is a companion protocol that is responsible for detecting and reporting errors to the source entity.

IP ADDRESSING

Each router or host on the Internet is assigned at least one unique global identity called an *IP address*. Names given to entities over the network could not replace IP addresses because the IP protocol uses the IP addresses to perform forwarding, and the *address resolution protocol* (ARP) maps IP addresses to their corresponding link layer addresses. The *domain name system* (DNS) maps IP entity names to IP addresses and vice versa.

Having a fixed length of thirty-two bits, IP addresses are formatted into a decimal notation such as: 128.244.65.18. Each IP address consists of two parts: *network number* and *host number*.

IP addresses are divided into five classes: A, B, C, D, and E (see Figure 2). In class A, the most significant bit of the leftmost byte is zero; that is followed by seven bits that represent the network number and twenty-four bits for the host number. That means that the network numbers 1 through 126 are class A networks. Note that

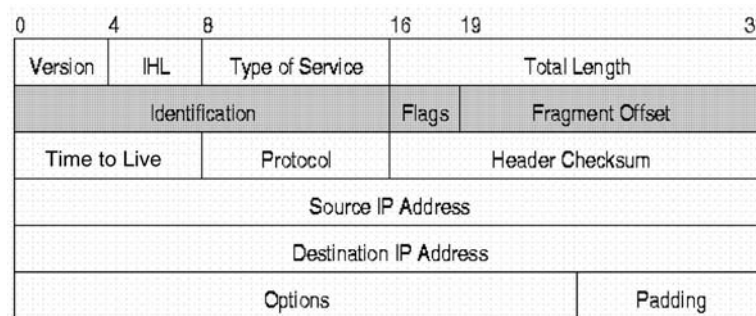

Figure 1: IP datagram header

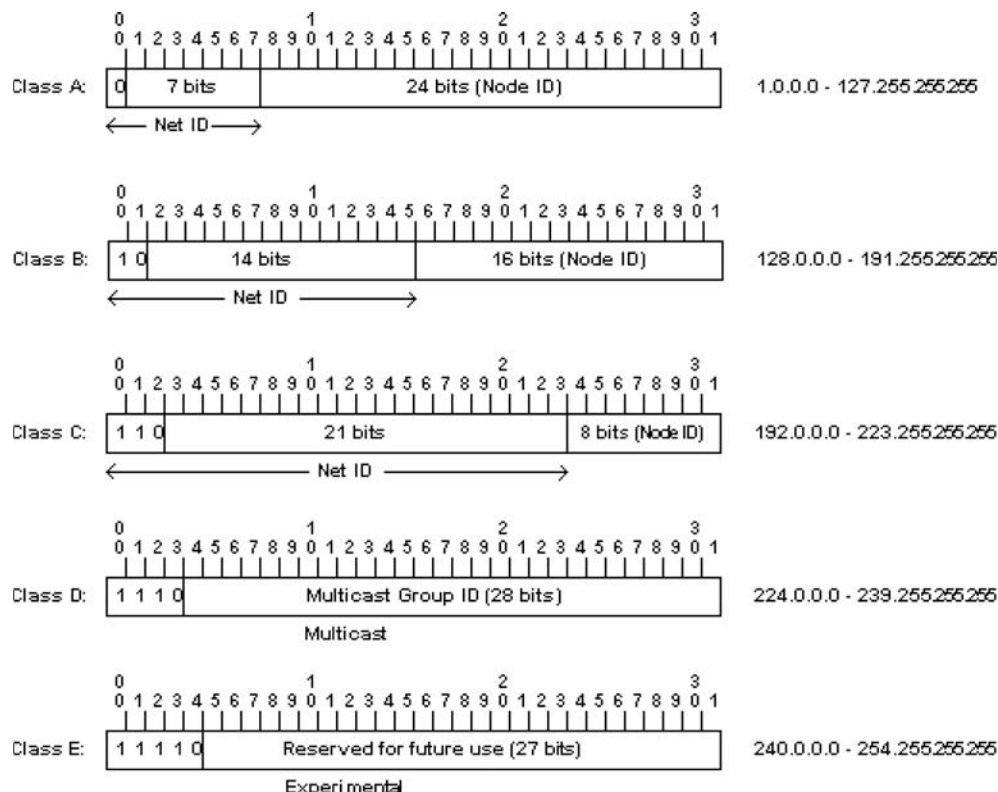

Figure 2: IP addresses classes. Source: www.cisco.com/warp/public/701/3.html

the network number 127 represents a local machine and is used for loopback.

In class B addresses, the two most significant bits of the leftmost byte are 10, followed by fourteen bits that represent the network number and sixteen bits for the host number. Class B network numbers are in range from 128 to 191.

In class C addresses, the three most significant bits of the leftmost byte are 110, followed by twenty-one bits for the network number and eight bits for the host number.

The above implies a maximum of 126 class A networks, each having as many as 16 million hosts. There are 16,000 class B networks with 65,000 hosts per network. Class C addresses provide approximately 2 millions networks, each consisting of 253 hosts. The Internet Corporation for Assigned Names and Numbers (ICANN) is responsible for assigning and mapping the network numbers.

Besides the aforementioned classes, class D is used for *multicasting*. This allows data to be sent to several destinations instead of just a single destination. Finally, class E is reserved for future use.

Network masks provide a method for specifying the network and host numbers in IP addresses. Having the mask and the IP addresses represented in binary notation would make it easier to identify the network number and the host number for each IP address. Classes A, B, and C have their own default masks. The default mask of class A addresses is 255.0.0.0; for class B, the default mask is 255.255.0.0; and for class C, the default mask is 255.255.255.0.

If we have the class A address 8.20.15.1, then:

```
IP address   : 00001000.00010100.00001111.00000001
Mask        : 11111111.00000000.00000000.00000000
Network number (binary)
Network number (decimal) : 8.0.0.0
Host number (binary) : 00000000.00010100.00001111.00000001
Host number (decimal) : 0.20.15.1
```

For class B, if we have the address 145.14.34.4, then:

```
IP address   : 10010001.00001110.00100010.00000100
Mask        : 11111111.11111111.00000000.00000000
```

```
Network number (binary) : 10010001.00001110.00000000.00000000
Network number (decimal) : 145.14.0.0
Host number (binary) : 00000000.00000000.00100010.00000100
Host number (decimal) : 0.0.34.4
```

For class C, if we have the address 196.10.33.2, then:

```
IP address   : 11000000.00001010.00100001.00000010
Mask        : 11111111.11111111.11111111.00000000
Network number (binary) : 11000000.00001010.00100001.00000000
Network number (decimal) : 196.10.33.0
Host number (binary) : 00000000.00000000.00000000.00000010
Host number (decimal) : 0.0.0.2
```

SUBNETTING

Subnetting is the process of logically dividing a given network into a group of smaller networks called *subnets*. Subnetting serves to organize large networks as a collection of smaller networks that follow the organizational structure of companies or organizations. Subnetting also improves performance through traffic control.

Internet addresses with subnetting are represented as:

<Network number><Subnet number><Host number>

The host number part is reduced to allow the subnet number to fit in the whole address. The trade-off in assigning bits from the host number to the subnet number is that each bit assigned would cut the maximum number of hosts to the half within the subnet and double the number of subnets in the network. Table 1 illustrates this point for class C addresses.

In the other classes, the table would be bigger because the host part is larger (sixteen bits for class B, twenty-four bits for class A), so potentially more subnetting designs are possible.

Table 1 Number of Subnets versus Number of Hosts in a Class C Network

Number Bits for Subnet	Number of Subnets	Number of Bits for Host	Number of Hosts
1	2	7	126 (128 – 2)
2	4	6	62 (64 – 2)
3	8	5	30 (32 – 2)
4	16	4	14 (16 – 2)
5	32	3	6 (8 – 2)
6	64	2	2 (4 – 2)

Table 2: Possible Designs for Class C Networks

Bits in Subnet Field	Number of Subnets	Bits in Host Field	Number of Hosts	Comments
2	4	6	62	Too few subnets
3	8	5	30	Good balance
4	16	4	14	Too few hosts

Table 3: Possible Designs for Class B Networks

Bits in Subnet Field	Number of Subnets	Bits in the Host Field	Number of Hosts	Comments
3	8	13	8,190	Too few subnets
4	16	12	4,094	Too few subnets
5	32	11	2,046	Good balance
6	64	10	1,022	Good balance
7	128	9	510	Good balance
8	256	8	254	Too few hosts

Table 4: Network Addresses and Host Addresses for a Class C Network with Subnet

Network Address	Valid Host Addresses
192.178.130.0	192.178.130.1 to 192.178.130.62
192.178.130.64	192.178.130.65 to 192.178.130.126
192.178.130.128	192.178.130.129 to 192.178.130.190
192.178.130.192	192.178.130.190 to 192.178.130.254
255.255.255.192	

In class A, the maximum number of subnets is 4,194,304 subnets with just two hosts in each one. In class B, the maximum number of subnets is 16,384 subnets with just two hosts in each. As illustrated in Table 1, class C subnetting design provides a maximum of 64 subnets.

An organization with class C network that requires seven distinct networks with a maximum number of twenty-eight hosts per each subnetwork can assign a three-bit subnet field to obtain a total of eight subsets, each with thirty hosts as illustrated in Table 2 below.

A larger organization with a class B network that requires eighteen subnetworks and a maximum of 445 hosts per subnetwork can design a solution based on the information in Table 3.

If a subnet mask of a class C network is 255.255.255.192, then it means that only two bits are assigned from the host number to the subnet number; the result is four subnets, each with as many as sixty-two hosts.

Let the organization's IP network be 192.178.130.0. If the previous subnet mask is used, then the organization's network will be segmented into four networks as shown in Table 4.

CLASSLESS INTERDOMAIN ROUTING

Because the Internet is running out of IP addresses and organizations do not fully utilize class B addresses, this class is getting more crowded and exhausted. A short-term solution for such problems is *classless interdomain routing* (CIDR) or supernetting.

The two primary functions of CIDR are (1) allocating address space throughout the Internet and (2) providing a method to aggregate routing information.

Address space allocation and the aggregation of routing information within a hierarchical topology is done automatically and smoothly for *single-homed* clients (i.e., those with one bandwidth provider). It is more complicated when clients are *multihomed*: They have multiple addresses with possibly different service providers. The routing information for these clients must be advertised by the supporting service provider, and whenever organizations change their service provider, it is recommended that these organizations migrate their address allocations to the new service provider's address space to save more address space and make routing more efficient and smooth.

The main idea of supernetting is to assign blocks from class C network numbers to a network service provider, where an organization using a specific service provider will be assigned mask subsets pointing to its provider address space. In this way, the hierarchical routing implies that any client using a service provider for network connectivity will be routed via its provider infrastructure even if the client or organization is multihomed.

Organizations that implement supernetting in their networks use IGPs that support classless routing such as OSPF. Older IGPs have the ability to receive supernet information but cannot distribute such information in their current routing domains.

The major benefits of using CIDR include: (1) preventing more occupation and exhaustion of class B address

space by allocating flexible and variously sized blocks of class C address space, and (2) controlling the growth rate of routing tables by significantly decreasing the entries in these tables.

Restructuring of IP addresses is required to apply CIDR. Instead of being limited to network prefixes of eight, sixteen, or twenty-four bits, prefixes can be used anywhere from thirteen to twenty-seven bits. Thus, blocks of class C addresses can be allocated to networks as small as thirty-two hosts—or as large as more than 500,000 hosts. This supports more flexibility in assigning addresses to an organization's network in ways that would meet its requirements.

The representation of CIDR address includes the standard thirty-two-bit IP address and the prefix that indicates the number of bits used for the network number. For example, in the CIDR address 211.78.4.39/24, the "/24" indicates that the first twenty-four bits are used to identify the network number; the remaining bits identify the host number (see Table 5).

Consider the block of 2,048 class C network numbers beginning with 192.24.0.0 and ending with 192.31.255.0 allocated to a single network provider whom we will call "RA." A supernatted route to this block of network numbers would be described as 192.24.0.0 with mask of 255.248.0.0.

If this service provider should connect six clients as in Table 6, then the service provider should assign addresses to the clients as follows:

C1: Addresses from 196.12.0.0 to 196.12.7.0. This block of networks is described by the route 196.12.0.0 and mask 255.255.248.0.

C2: Addresses from 196.12.16.0 to 196.12.31.0. This block is described by the route 196.12.16.0, mask 255.255.240.0.

C3: Addresses from 196.12.8.0 to 196.12.11.0. This block is described by the route 196.12.8.0, mask 255.255.252.0.

C4: Addresses from 196.12.12.0 through 196.12.15.0. This block is described by the route 196.12.12.0, mask 255.255.252.0.

C5: Addresses 196.12.32.0 and 196.12.33.0. This block is described by the route 196.12.32.0, mask 255.255.254.0.

C6: Addresses 196.12.34.0 and 196.12.35.0. This block is described by the route 196.12.34.0, mask 255.255.254.0.

To make this example more realistic, assume that C4 and C5 are multihomed through "RB," another service provider. Further assume the existence of a client "C7" who was originally connected to "RB" but has moved to "RA."

C7: Allocate 196.32.0.0 through 196.32.15.0. This block is described by the route 196.32.0.0, mask 255.255.240.0.

For the multihomed clients, we will assume that C4 is advertised as primary via "RA" and secondary via "RB"; C5 is primary via "RB" and secondary via "RA."

Assume that "RA" and "RB" are connected via some common "backbone" provider "BB." Result advertisements from "RA" to "BB" will be:

C4 primary advertisement: 196.12.12.0 to 255.255.252.0.

C7 primary advertisement: 196.32.0.0 to 255.255.240.0.

Table 5: Examples of CIDR Prefixes

CIDR Prefix	Number of Equivalent Class C	Number of Host Addresses
/27	1/8	32
/26	1/4	64
/25	1/2	128
/24	1	256
/23	2	512
/22	4	1,024
/21	8	2,048
/20	16	4,096
/19	32	8,192
/18	64	16,384
/17	128	32,768
/16	256 (= 1 class B)	65,536
/15	512	131,072
/14	1,024	262,144
/13	2,048	524,288

Table 6: Example of Class C Network Allocation

Client	Number of Equivalent Class C Networks	Number of Host Addresses
C1	8	≤ 2,048
C2	16	< = 4,096
C3	4	< = 1,024
C4	4	< = 1,024
C5	2	< = 512
C6	2	< = 512

Remainder of RA primary advertisement: 196.12.0.0 to 255.248.0.0.

For RB, the advertisements must also include C4 and C5 as well as its block of addresses. Result advertisements from "RB" to "BB" will be:

C4 secondary advertisement: 196.12.12.0 to 255.255.252.0.

C5 primary advertisement: 196.12.32.0 to 255.255.254.0.

Remainder of RB primary advertisement: 196.32.0.0 to 255.248.0.0.

NETWORK ADDRESS TRANSLATION

Network address translation (NAT) is another short-term solution along with CIDR and subnetting to the scarce IP addresses limitations and scaling problems. A *stub domain* is a domain that handles network traffic from and to hosts inside the domain. Whenever a communication outside the stub domain is needed, the IP addresses—only the ones communicating outside the domain—should be reformed to be globally unique. The IP addresses inside one's stub domain are not globally unique and are reused in many different domains.

Here comes the role of NAT, which is nothing but a router function or model that is set to a stub border router. At the end points of a stub domain, where it shares borders with other outside domains and networks, NAT must be configured at these end or exit points, having the same translation table in all distinct end points within the same domain.

NAT's tables carry two parts of data: (1) the reusable addresses, also known as *local addresses*, that are used internally in a stub domain; and (2) the global addresses that are unique and used to communicate with global networks. NAT provides external communication ability to the Internet or other networks and domains by translating these reusable addresses and mapping them with unique global IP addresses.

To illustrate how NAT works, let's have two stubs, A and B, that internally use class A address 20.0.0.0. Stub A's NAT is assigned the class C address of 198.76.29.0, and stub B's class C address is 198.76.27.0. When stub A host 10.40.66.5 wants to send datagrams to stub B host 10.88.12.21, it uses the global unique address 198.76.27.4 for the destination's address and sends the datagrams to its corresponding router. The stub router translates the source host address 10.40.66.5 in the IP header to globally unique address 198.76.29.15 and uses a static route for the net 198.76.0.0; as a result, the packets are sent to the next router in a different network. Before the datagram is transmitted to the destination, stub B router maps the destination's address 198.76.27.4 in the IP header to the available host that owns this global address and forwards the datagram to the that host.

The address translations used by NAT are done transparently. Both host and routers require no changes or knowledge about the mappings or translations of local addresses to global ones.

Having NAT installed, end-point stub routers never advertise the local addresses to the global network's backbones; global information from the backbones, however, can be advertised via the stub domains.

Because the hosts in the backbone cannot tell which address or source host has sent the packets, this whole matter increases the privacy of the hosts. As useful as it is, there is a negative effect: Security can be breached easily and the tracking methods could become difficult because locating the IP address would be challenging: It is unknown to the global backbone. Such scenarios are used in sending junk mails, hacking, and otherwise abusing the net. Other NAT drawbacks include (1) potential misaddressing problems, (2) the need to use sparse end-to-end matrices to avoid having huge translation tables

that would affect performance, (3) difficulties in running some applications, and (4) problems with *simple network management protocol* (SNMP), DNS, and other protocols.

FRAGMENTATION AND REASSEMBLY

Sometimes a large datagram—that is, one larger than the MTU—reaches a network. In such a case, the router receiving the datagram either drops it and returns an ICMP message saying “Datagram too big,” or it fragments the datagram into smaller datagrams that can be handled by the network. The latter option is called *fragmentation*.

When the fragments reach the destination host, they will be recombined in a process known as *reassembly*.

The IP address header consists of three vital parts for the fragmentation and reassembly process: identification, fragmentation flags, and fragmentation offset.

The *identification* is a sixteen-bit unique number assigned by the sending entity. Via the identification bits, the destination host can recognize different arriving fragments and assemble the ones with the same identification, along with the same source, destination, and protocol identification to form the original datagram.

The *fragmentation flags* section is a three-bit number divided into three parts: the *must be zero* (MBZ) bit, which is always set to zero; the *do not fragment* (DF) bit; and the *more fragments* (MF) bit.

If the DF equals zero, then the routers can fragment this datagram if necessary. If the DF is set, then the datagram will not be fragmented under any circumstances; if it cannot be delivered without fragmentation, then it will eventually be dropped.

DF	(1 bit)
Value	Description
0	Fragment if necessary
1	Do not fragment

When set, the MF flag indicates that more fragments can be expected and this one is not the last. But if the MF is zero, this is the last fragment.

MF	(1 bit)
Value	Description
0	No more fragments (last fragment)
1	More fragments follow this fragment

The fragmentation offset, which is thirteen bits long, represents the position or order of the fragment in the whole datagram; in other words, it identifies the order or sequence of the fragment relative to the others. The first fragment always has the offset of zero.

These fields provide enough information to reassemble datagrams.

The fragmentation process works as follows: Several new datagrams (i.e., fragments) that comply with the current network MTU are created. The original datagram IP header is copied verbatim to the new datagrams IP headers. The data of the original datagram are divided into eight-byte blocks and distributed among the newly created datagrams. An eight-byte block is called a *number of fragment blocks* (NFB). Every fragment must be assigned

an integral number of the eight-byte blocks, except the last fragment. In all fragments, the total length field is set to the size of the data in the fragment. In the first fragment, the fragment offset is set to zero. For the other fragments, the fragment offset is set to the value of the fragment offset in the original datagram plus the summation of the NFB value of the preceding fragments. Finally, the MF flag is set to 1 in all fragments except the last.

It is possible that the source hosts perform the fragmentation instead of the routers, but that would necessitate a *path MTU* discovery so the source host knows the smallest MTU value along the path to the destination. Path MTU discovery is not always guaranteed to succeed because it depends on ICMP messages, which are blocked by some networks as a countermeasure to *denial of service* (DOS) attacks.

When a fragment reaches its destination, it is checked to see if it belongs to a datagram that is being currently assembled or to a new datagram. If the just-arrived fragment belongs to a new datagram, then a new data buffer and a bitmap are allocated. The bitmap is used to keep track of which fragments have arrived.

If all fragments belonging to a datagram arrive within a specified time period, then the assembled datagram is passed to the transport layer; otherwise, the partially assembled datagram is dropped.

To give an example of fragmentation and reassembly, we have a datagram with 624 bytes of data; the MTU is 544 bytes (see Figure 3).

Fragmentation of the datagram into two fragments will solve the problem. The first fragment is shown in Figure 4, and the second (last) fragment is shown in Figure 5.

4 bits	8 bits	16 bits	32 bits	
Ver = 4	IHL = 5	Type of service	Total length = 644

ROUTING

Routing is the process of passing a packet from one node to another in a network until this packet reaches its intended destination. The network nodes that are dedicated to routing are called *routers*. Routers perform routing through tables known as *routing tables*. For example, in Figure 6, the routing table in router A would tell whether a packet going from PC 1 to a server will go through router B or C. Building routing tables could be done either manually (i.e., *static routing*) or automatically (i.e., *dynamic routing*).

Static Routing

Static routing is a simple method in which users manage and arrange routes through a relatively small network. To do so, one should either draw routing diagrams (usually done in real-life scenarios) or create routing tables.

Assume that R1, R2, and R3 are three routers for this network. A, B, and C are selected hosts in the network; each exists in a different subnet. Another host, D, in another external network is connected with this network. Assume the network address is 198.10.12.0 of class C (255.255.255.0) and let the subnets' addresses be as shown in Figure 7.

Figure 6: Simple network with four routers

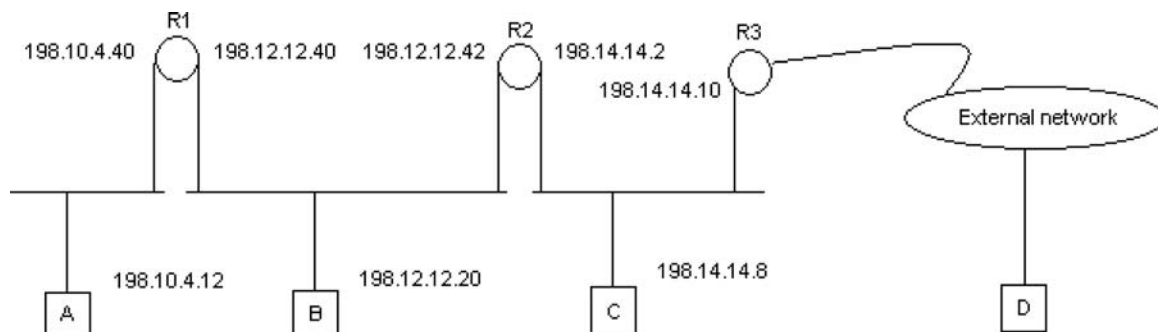

Figure 7: An example of a network that uses static routing

For the network to communicate with the external network, note that NAT is supposed to be installed on router R3 router, the end-point router.

The next step is to pinpoint the *default gateways* (dg) and connect them between the nodes (host and routers) and their default routers or gateways (see Figure 8). After that, specific routes' expressions are computed and supplemented to provide particular complementary routes along the default gateways to control the flow to the opposite side (to the left in this scenario) without the need to pass through default gateways. These expressions simplify the routing paths between nodes in understandable and easy notations such as $R(X, Y, \rightarrow Z)$, which means there is a route to the network subnet X that has the mask Y through the gateway Z.

Figure 9 represents the complete diagram that simulates a static routing principle for this network.

To configure the routes of a network in real life, we simply use the *route* add* command for each subnet address connected to its designated gateway. To do that in the previous scenario, it would be similar to the following:

To configure host A routes:

```
route add 198.12.12.0 mask 255.255.255.0
198.10.4.40
```

If host A is connected to another router that connects to a subnet in the opposite direction (to its left), then that route should be added as well.

To configure host B routes:

```
route add 198.10.4.0 mask 255.255.255.0 198.12.
12.40
route add 198.14.14.0 mask 255.255.255.0
198.12.12.42
```

To configure host C routes:

```
route add 198.12.12.0 mask 255.255.255.0
198.14.14.2
route add (External Address) mask 255.255.255.0
198.14.14.10
route add 198.10.4.0 mask 255.255.255.0
198.14.14.2
```

One can monitor the applied routing table in the local network by running *netstat*** command with the *r* and *n* options—*r* to display routing table and *n* to show IP addresses in their numeric notation (see Figure 10).

The result shows destinations (hosts or routers) and their corresponding default gateways along with other features such as the netmasks, interfaces, and metrics.

Figure 8: An example of a network that uses static routing with default gateways added

m in the R expressions stands for the mask = 255.255.255.0

Figure 9: An example of a network that uses static routing with routing expressions added

* Available for Windows, Linux, and Unix Systems.

* Available for Windows and Unix Systems.

Figure 10: An example of retrieving the local network routing table using netstat

Another method to configure routes in a network is to use ICMP route redirect messages. This method cuts the complexity of declaring routes for the hosts all over the network; it only requires specifying routers' special routes.

Note that there are no routes expressions for the hosts. This will lead to datagrams routing only through default gateways, which will forward them using the default gateway or the assigned routes. This method is certainly easier, yet it would affect the performance and the traffic by depending only on the default gateways.

Dynamic Routing

Dynamic routing is less intuitive but more effective and easily scalable when compared to static routing. It is also more resilient to failed routers than static routing because routers can automatically update their routing tables without administrator intervention. Dynamic routing can be classified into three broad categories: *distance vector routing*, *link state routing*, and *policy-based routing*.

Distance Vector Routing

Distance vector routing is a protocol that particularly applies the *Bellman-Ford algorithm* to find the optimal paths in a network by utilizing vector, direction, and distance concepts to gather the required routing information and tables.

Routing information protocol (RIP) is one of the most common protocols to apply distance vector routing to compute the paths between the routers in a network. RIPv2 is the second version of the original RIP protocol and has nearly replaced RIPv1.

In a RIP network, routers exchange messages with each other that contain their own routing table entries represented as destination IP addresses and their corresponding distances computed in terms of hops. In this way all of the nearby routers acquire the most updated and new routing data and update theirs accordingly. The

updated data aim to reduce the path distance by minimizing the number of crossed hops.

Quagga, a free software suite, can be used to configure RIPv2 routing, among other routing protocols, on Linux systems.

Link State Routing

Link state routing is a competitor to distance vector routing; with the latter, the routers exchange information only with the neighboring ones, but in link state routing the routers exchange information with all other routers in the network. A router sends messages containing the information (routing metrics) that are identified as *link state advertisements* (LSAs) to all neighboring routers. These routers exchange the advertisements with their neighbors as well and so on. This method of exchanging messages is also known as *flooding*.

The flooding of advertisements is commenced whenever updates occur. If there are no route updates, then there will not be any messages exchanged—unlike the distance vector, which depends on periodic broadcasting of messages.

This grants the network more efficiency and stability because there will not be that much traffic caused by the multicasting of the advertisements. It is only activated whenever route updates occur and does not necessarily include all the routers in the network, only those relevant to these updates.

Link state routing, then, is more efficient and stable by maintaining a degree of traffic control over the distance vector routing. In addition, distance vector routing has a lot of problems such as the convergence and count-to-infinity dilemma; these distinguish the link state over the distance vector protocols.

One of the most common link state routing approaches is the *open shortest path first* (OSPF). This protocol uses specific algorithms—basically, the *Dijkstra algorithm*—to compute the shortest routes between nodes in the network by forming a tree with routers as nodes. It then tries to

figure out the distances and costs between these nodes to conclude the best routes.

OSPF passes around different types of packets that sum up the whole process (see Table 7).

The *hello* packets are distributed usually during the initiation to find out neighboring routers. The *database description* and *link state request* packets are engaged in the creation of adjacency and contiguity connections among routers. The *link state update* and *link state acknowledgment* packets are the core of the routes and metric update as well as the flooding part.

All messages or packets share an ordinary twenty-four-byte header, which is formatted as shown in Figure 11.

OSPF provides logical arrangements of networks such as where nodes can be encapsulated within areas. This reduces the traffic and the congestion of updates flooding beyond network capacity. It also cuts down the unnecessary update messages through other areas where these messages are not really claimed. Although the network topology can be divided into several different areas, all of these areas should be joined to a central one called the *backbone area*.

Policy Routing

Policy routing is a flexible way of routing that allows customizable routing of packets according to the policies and rules with which a specific organization’s traffic should comply. Network administrators are able to control routing mechanisms as well as packet flows in their network system by publishing defined policies that policy-based routing protocols must follow.

Policy routing is different from the other dynamic routing protocols (distance vector and link state). It is an exterior gateway protocol (EGP) that is implemented in multi-autonomous systems, not a single one.

Border gateway protocol (BGP) is a policy-based routing protocol that uses a path vector algorithm to discover the optimal path. However, if routing policies are defined, it adopts these policies as its method in resolving the route selections. BGP uses TCP as a transport mechanism in message exchanges. The main functionality of BGP systems is to link with other BGP autonomous systems and exchange routing and reachability data to help in path selection without breaking any policy enforced in the network traffic.

Different messages are exchanged in BGP; each message has its own distinct format and header. BGP messages are divided into four categories according to its type: open, update, notification, and keepalive messages. *Open* messages are transmitted right after connection between hosts is established. A *keepalive* message is sent to the source to confirm the open message reception. *Update* messages transport the routing information to the nodes and are also used as a way to advertise routes. Keepalive messages are exchanged frequently to ensure that connectivity remains alive between hosts and prevent any connection timeout. *Notification* messages are passed around on any error detection.

MULTICAST ROUTING

Multicast routing is a mechanism that allows an IP datagram to be delivered to a host group—that is, multiple hosts represented in a single IP address. In a multicast, the sent datagram is neither promised to be delivered to all members of the destined group host nor delivered in the exact sequence as other datagrams.

There are no restrictions for any host in joining or leaving any host group at any time. Also, there are no limitations on the total number of hosts permitted in host groups or the locations of host groups. A host does not need to belong to a certain group to be able to have datagrams sent to it. A host can join more than one group at the same time.

A class D IP address is the one that handles the multicast technique. The first four bits—which are the high-order bits of (1110)—followed by the host group ID together represent the multicast group address or class D IP address. It ranges from 224.0.0.0 to 239.255.255.255. Some of the group addresses are already assigned by the Internet Assigned Numbers Authority (IANA); these addresses are called *permanent host groups*. For example, 224.0.0.1 is allocated to the permanent host group of all IP hosts and gateways in that subnet.

To perform multicasting, specific kinds of routers that support multicasting, called *multicast routers*, are employed; they could be separate from or work with normal routers. A multicast router in a certain subnet could be linked to another multicast router in a different subnet, and the latter could be linked to another, and so forth, creating what’s called a *multicast backbone* (Mbone). Mbone is a collection of autonomously administered multicast regions, each specified by one or more multicast routers.

The *Internet group management protocol (IGMP)* is just a reporting protocol, similar to ICMP, but its purpose is to allow hosts to send reports throughout the network to inform the neighboring multicast routers about their “joins” or memberships to host groups.

Table 7: OSPF Packets Types

Type	Packet Name

Figure 11: OSPF header fields

From time to time, multicast routers transmit query messages to get the latest information about the memberships to a particular region or network. Whenever those queries are not replied to, the multicast router surmises that there are no members in that group and that it should not be involved with any forwards or multicasts. Any time a host joins that group (or any empty group), it should instantly send a report notifying the multicast routers that the host group has a member and is qualified to receive multicasts.

As mentioned earlier, only multicast routers have the ability to forward multicast datagrams; therefore, one method that allows routers that are missing multicasting support to send multicast datagrams and link with other multicast-enabled routers is called *tunneling*. Tunnels are virtual point-to-point links that allow the multicast datagram to be encapsulated in a normal (unicast) datagram in order to be transferred freely through available gateways.

Different algorithms are involved in multicast routing: *distance vector multicast routing protocol* (DVMRP), *multicast open shortest path first* (MOSPF), and protocol-independent multicast (PIM). Each region could choose any of these algorithms, forcing all multicast routers in that region to use only the same algorithm. All regions, however, can be linked together despite algorithm differences through a common region called *region backbone*, which runs the *distance vector multicast routing protocol* (DVMRP). This way, only border multicast routers in the regions should be able to interconnect with the backbone through the DVMRP.

DVMRP uses several remarkably different algorithms. *Truncated reverse path broadcasting* (TRPB), *reverse path broadcasting* (RPB), and *reverse path multicasting* (RPM) are different algorithmic approaches that handle the forwarding of multicast datagrams and the creation of distribution trees distinctively. Whereas TRPB concentrates on creating a shortest-path distribution tree with the ability to prune all unnecessary interfaces, RPB is less efficient in a way that it does not have the pruning feature, resulting in datagram duplication. However, a much better solution in forwarding datagrams is to use RPM, which holds out the distribution tree of all source and group pairs.

DVMRP multicasts periodically so that it can manage to deliver the datagrams to new members of the destination host groups. Hence, this brings some scaling and performance difficulties to the surface.

MOSPF, on the other hand, optimizes the path between the source and destination by computing the shortest possible distance between them. By using a type of spanning tree called *Steiner tree*, which preserves group members' routes and statistics, a router attempts to forward the datagrams within the optimal path between the source and the potential host group's destinations.

Although, in this manner, path utilization could be maximized between source and group, the overall inter-network utilization is more often disrupted.

In the forwarding process, each router located in the multicast datagram's path must preserve cached details (called *forwarding cache*) that hold information about the router from which the datagram was received (the *upstream node*) and the interfaces the datagram should head out of (the *downstream interfaces*). Each entry in the

cache is based on two elements: (1) the local database that indicates the router's directly linked nodes and their corresponding group memberships, and (2) the shortest path tree that connects the source to remotely bound group members.

Unlike the previous protocols, PIM is a flexible multicast pattern that does not rely on any particular unicast protocol. It has the ability to get along with the entire set of currently implemented unicast algorithms. *Sparse mode PIM* (PIM-SM) and *dense mode PIM* (PIM-DM) are two common implementations of this protocol.

In PIM-SM, a router receives join and prune messages from neighboring routers. These messages serve to guide the router to forward datagrams to specific interfaces. The virtual point at which join and prune messages are intersected to accumulate a tree with only active members (sending and receiving nodes) is called the *rendezvous point* (RP). The RP is the most fundamental component to this protocol; when a router wants to forward the datagram, it sends the RP the same matches with the receiving nodes where they notify the RP. Once the data stream begins to flow from sender to RP and then to receiver, the routers positioned along the forwarding path refresh and update the path automatically to avoid any unnecessary gateways or branches until the forwarded datagrams reach the designated group members.

PIM-DM, on the other hand, considers all downstream nodes to be eligible to receive the multicast datagrams, so basically the network is flooded with the multicast datagrams and *reverse path forwarding* (RPF) is used to suppress the multicast datagrams' duplication. After flooding, if any branch in the network does not have group members, then it is pruned for a certain period. Whenever a new member joins a pruned branch, the updated router forwards the datagram to that branch to deliver it to the group member, changing it to an active branch.

In summary, the main distinctions between PIM-DM and PIM-SM are that in the former there are no scheduled joins monitored or any periodic updates (just clear prunes and grafts) and there is no RP.

PIM-DM and PIM-SM can be blended together in the same network, but a PIM-DM router cannot be set to be downstream of a PIM-SM router.

QUALITY OF SERVICE ROUTING

Quality of service (QoS) is the capability to provide guarantees that a requested service will be delivered according to a certain standard of quality. QoS involves assigning different priorities to different users or data flows. This contrasts with typical Internet behavior, which is based on *best effort delivery*. In best effort, users and data flows are treated equally. Best effort is suitable for applications such as e-mails and FTP, but it may not be suitable for newer applications such as streaming multimedia IP telephony. QoS is more importance for limited capacity networks.

In the following subsections, three QoS protocols will be presented: differentiated services (DiffServ), integrated services (IntServ), and multiprotocol label switching (MPLS).

Differentiated Services

Differentiated services (DiffServ) is based on classifying packets and handling them according to this classification. The DiffServ protocol itself does not have standard classifications but recommends four such classes. The establishment of classes is left to the network operators. Packet classification may depend on source address, destination address, or traffic type. Packets can have DiffServ markings that request certain service, but DiffServ routers are not obliged to honor these markings. DiffServ recommends four classes of services: (1) *default*, which is equivalent to best-effort service; (2) *expedited forwarding* for low-loss, low-latency traffic; (3) *assured forwarding*; and (4) *class selector*, which is equivalent to the IP header's precedence field.

Integrated Services

Integrated services (IntServ) was proposed as an approach to provide end-to-end QOS that real-time applications require by explicitly handling available resources to distinguish one packet stream from another. IntServ has four fundamental core components that establish such QOS integrated service: (1) packet scheduler, (2) classifier, (3) admission control, and (4) resource reservation protocol (RSVP).

The *packet scheduler* uses queuing and sometimes timers to handle the forwarding and policing of different packet streams. Packet scheduling is implemented at the data-link layer. To control the traffic and classify the different packet streams, each packet is mapped into a certain class, depending on some header value or additional classification number appended in the packet. Packets of the same class receive the same management from the packet scheduler. All of that is performed by the *classifier*.

Admission control manages the decision making in a router or host to receive a QOS for a new flow without influencing earlier guarantees. It is invoked at each host or router in the network to either accept or reject QOS requests via special route. The admission control algorithm must be consistent with the service model, and it is logically part of traffic control. The major role of the admission control is guaranteeing that QOS requests are satisfied. It also has important roles in imposing some administrative policies such as authentication upon resource reservations, accounting, and administrative reporting.

The final component of IntServ is the *resource reservation protocol*, which is needed to preserve a flow-specific state in the end-point nodes residing in the path of the traffic stream. Its main purpose is to explicitly signal the QOS requests of a specific application's traffic through the interfaces (nodes) located in the boundary regions along the taken route. Whenever a required bandwidth is reserved at the end points along the path, the application can commence the signaling or transmitting of packets. To simplify things, the signaling responsibility for transmitting QOS request is done through the RSVP that notifies routers about the application program's QOS request.

Two parameters are used to generally describe the operation of resource reservation: (1) the *flow spec*, which

describes the resource quantity to be reserved; and (2) the *filter spec*, which describes the packet subset obtaining those reserved resources.

Multiprotocol Label Switching

A separate mechanism that is considered a fundamental section of QOS is called *multiprotocol label switching* (MPLS) because it is feasible in any network layer protocol and depends on label-based forwarding in transmitting packets.

MPLS confers QOS aims and advantages. It provides a great deal of flexibility to divert and control traffic streams, avoid network congestion spots and delays, and provide QOS utilities.

In any network, each router is independently capable of choosing the next router or hop and to thereafter forward the packet, relying on both the vital information concealed in the packet's header and the routing algorithm it is implementing.

In details, packets are divided to *forwarding equivalence classes* (FECs). These are, in turn, appended in the routing tables and referred to its designated next hop. This means that all packets belonging to a particular FEC will go along the same route or multipath routes associated with that FEC.

Each FEC is assigned a particular small identifier called a *label*. Once a packet arrives at a MPLS-supported router called a *label-switching router* (LSR), certain algorithms (the type depends on the packet's header) map the packet into its corresponding FEC. After that, the FEC-associated label is tagged to the packet before forwarding. Now the packet is ready to be forwarded to the next router, and instead of analyzing the packet each time it arrives at a router, the label associated with that packet (only representing FEC) is used as an index in the routing table to find out the path to the next hop; this is called a *label-switching path* (LSP).

To achieve a certain degree of QOS, the *precedence* and *class-of-service* fields represented in the header of a packet can be referenced from the label, avoiding analysis and allowing faster access. This means that labels are not only simple representations or indices to FECs but also class-of-service and precedence providers. In case of precedence, FECs prioritized to higher priority will use a higher-priority LSP, and the lower priority FECs will use lower-priority LSP.

Label distribution protocol (LDP) is responsible for the distribution and preservation of the relationship between the labels and FECs in MPLS. Other protocols may replace LDP such as *constraint route label distribution protocol* (CR-LDP), and resource reservation protocol-traffic engineering (RSVP-TE).

MOBILE INTERNET PROTOCOL

In the network, a node must be attached and assigned an IP address so that it can receive datagrams transmitted to it or it will never receive the datagrams. Having the capability to both exchange datagrams and change the point of attachment in the network is achieved through the

mobile IP's mechanism. This mechanism usually applies to nodes that are connected to the network or Internet via a wireless link.

Although this mechanism allows a node to change its point of attachment to a network; the node preserves its own IP address throughout the changing of networks or subnets.

To preserve exchanging datagrams in both the old network and the newly visited one, special routers called *home agent* and *foreign agent* are needed. The home agent is situated in the mobile's node home (permanent network) and delivers the datagrams destined to the mobile node when it is away or attached to another network (foreign network). The foreign agent is situated in the mobile's node visited (i.e., foreign) network and serves the mobile node as long as it is a registered guest. It also delivers the datagrams destined to the mobile node tunneled by the home agent.

A mobile node is not necessarily a host that can attach to different networks. It could be a router that is mobile along with its network or an entire set of mobile networks.

In a home network, the mobile node functions naively. As it enters a foreign network, the mobile node acquires a new temporary IP address called the *care-of address*. The mobile node then registers the newly acquired care-of address to the home agent through distribution of *registration requests* and *registration replies* messages. This process is inverted (i.e., deregistration) when the mobile node returns back to the home network by also using the registration requests and replies.

This registration allows the home agent to seize the datagrams destined to the mobile node's home IP address and then tunnel and transmit those datagrams to the mobile node's care-of address (which might be transmitted directly to the node or to the foreign agent first). The home agent checks the destination IP address in the header of the datagram to see if it is exactly equivalent to any of its mobile nodes registered in a foreign network and accordingly tunnels or drops the seized datagrams. Tunneling also enables the exchange of ICMP messages redirected to the original senders if some trouble or error is generated during the datagram's transmission; this is called the *tunnel soft state mechanism*.

Mobile nodes have the ability to send datagrams directly to routers or hosts using available routing algorithms. Datagrams sent from mobile nodes are certainly no compelled do not have to go to the home agent.

There are two forms of care-of addresses: (1) the foreign agent care-of address and (2) co-located care-of address. The *foreign agent care-of address* represents the IP address of the foreign agent and is provided by *agent advertisement* messages. This means that the datagrams sent by the home agent to the mobile node of such a care-of address will arrive first at the foreign agent. The foreign agent itself will decapsulate the mobility and additional headers off these tunneled datagrams and send them to the mobile node. The advantage of this form is that it allows multiple mobile nodes to share the same care-of addresses, which will save many IP addresses for other uses.

On the other hand, the *co-located care-of address* is the one obtained by other external mechanisms to represent the IP address of the mobile node as a local IP address. It could be a temporary IP address automatically generated by the node itself via the *dynamic host configuration protocol* (DHCP) or an assigned permanent IP address to be used whenever the mobile node is in a foreign network. In this form, the mobile node itself represents the care-of address and is responsible for the tunneling and decapsulation of the received datagrams. The advantage of co-located care-of address is the absence of any intermediate (foreign agent) intervention.

In a foreign network, the mobile node cannot exchange datagrams with the foreign agent using direct and standard IP-routing protocols because those protocols rely once and for all on the destination IP address (in this case, the home IP address of the mobile node) presented in the header of the datagrams. The solution is that the foreign agent and mobile node have a common network gate or interface with the attaching link between both of them in which the mobile node and the foreign agent seize the use of standard IP-routing protocols and exchange packets via the link layer level.

INTERNET PROTOCOL 6

The Internet has become a basic element in every aspect of life, leading to huge demands and tremendous consumption of IP addresses to host different Web applications and commercial Web sites, and so on. This demand has steadily grown, making IP addresses scarcer each day. A solution to this problem is the new IP protocol called *IPv6*.

The main improvements of IPv6 over the current IPv4 are the new address and header structures. The IPv4 header is shown in Figure 12, and the IPv6 header appears in Figure 13.

0bits	4	8	16	24	31
Version	IHL	Service Type	Total Length		
Identifier			Flags	Fragment Offset	
Time to Live		Protocol	Header Checksum		
Source Address (32bit)					
Destination Address (32bit)					
Options + Padding					

Figure 12: The IPv4 header

IPv6 Header Structure

The *version* represents the protocol used to send this packet. The *class* (traffic class) is used only by the source hosts and forwarding routers to specify certain classes and priorities provided for the IPv6 datagram. The purpose is to provide some QOS capabilities such as integrated and differentiated service models for the new IPv6 packets in a simpler manner than the complicated configuration of classifying streams.

The *flow label* is used to specify the type of QOS handling required for a datagram sent from a specific source address to a specific destination. Datagrams that share the same flow must be sent with the same source address, destination address, and flow label, and datagrams that do not belong to any flow have a flow label value of 0.

Payload length is the size of the rest of the datagram, including the extension headers.

The *next header* describes the header type following this header. The values are similar to that used for IPv4. Table 8 shows some of the possible values.

Table 8: Next Header Field Possible Values

Decimal Value	Header
0	Hop-by-hop options
1	ICMP
2	IGMP
6	TCP
17	UDP
41	Encapsulated IPv6
43	Routing
44	Fragment
46	RSVP
50	Encapsulating security payload
51	Authentication
58	ICMPv6
59	No next header
60	Destination options

The *hop limit* field is the maximum number of hops that this datagram should go through. On each passed hop, the hop limit is decremented by one; if the value reaches zero, then the datagram is dropped.

The *source address* represents the 128-bit address of the source host, and the *destination address* represents the 128-bit address of the destination host.

In addition to the standard header, a set of additional extension headers cooperates with it. The set should have the same sequence of order summed up in the following:

1. Hop-by-hop options header
2. Destination options header (for mediatory destinations)
3. Routing header
4. Fragment header
5. Authentication header
6. Encapsulating security payload header
7. Destination options header (final)
8. Upper-layer header

When the next header field value is equivalent to 59 in the IPv6 header or any extension header, this reveals that no header follows.

The Hop-by-Hop Options Header

The *hop-by-hop options header* is used to set some values and options inspected by each hop (node) along the datagram's delivery route to the destination (see Figure 14).

The *next header* defines the header type to follow this header.

The *header extension length* is the total size of the hop-by-hop options header without the first eight octets, and it is presented in eight-octet units.

Options is a variable field; its length can be any multiple of eight-octet blocks, and it describes some the pre-defined options such as the *pad 1*, which corresponds to one-octet padding; *pad n*, which corresponds to *n*-octets padding; and other options.

Destination Options Header

The *destination options header* is used to set certain options inspected only by destination nodes along the datagram's delivery route. This header might represent the destination options for both the intermediate destinations and the final destination but in two separate headers

Figure 13: IPv6 header

Figure 14: Hop-by-hop options header

Figure 15: Destination options header

Figure 16: Routing header

Figure 17: Fragment header

(see Figure 15). The fields included in this header have the same description as the ones included in the hop-by-hop options header.

Routing Header

The *routing header* identifies the nodes (routers) to be visited along the datagram's route to the destination (see Figure 16).

The *routing type* indicates a particular routing header variant. The *segments left* field is the number of remaining route nodes still to be visited preceding the destination; the value is decremented in each visited router. If segments left is equal to 0, then the receiving node ignores this header and advances to process the next one.

The *type-specified data* is a multiple of an eight-octet variable that is dependent on the routing type. If routing type is 0, then the type-specified data is nothing but the addresses of the intermediate destinations to be visited.

Fragment Header

In the *fragment header*, fragmentation takes place in a separate header extension; this is unlike the IPv4 datagram, which is included in the same header. The fragment header is used whenever a source node needs to transmit a datagram that is larger than the MTU allowed across the path leading to the destination.

Unlike IPv4, fragmentation is carried out only by the source node, not by routers along the destination path (see Figure 17).

The *reserved fields*, which are zeros, are ignored in each receiving node and preserved for future needs. The *fragment offset* identifies the order or sequence of the fragment relative to the start of the fragmentable part of the original datagram.

The *more flag* (MF) section is either 1, which means more fragments follow; or 0, which means the header carrying datagram is the last fragment.

The *identification* is a unique number assigned by the source node and specifies a single value to all fragments of the original datagram. In this way, the destination host can recognize different arriving fragments and assemble the ones with the same identification, along with the same combination of source and destination addresses.

To send datagrams that are too large to fit in the MTU of the delivery path, source nodes may apportion the datagram into several fragments, each considered as a separate packet to be reassembled in the end at the destination node as presented in Figure 16 (see Figure 18).

The Authentication Header

The *authentication header* offers data verification, data integrity, and data origin authentication for datagrams. It also offers protection against replays, an optional service chosen by the receiving node whenever a *security association* (SA) is present (see Figure 19).

The *payload length* identifies size of the authentication header represented in eight-octet units. If the authentication is zero, then the value of this field equals 2.

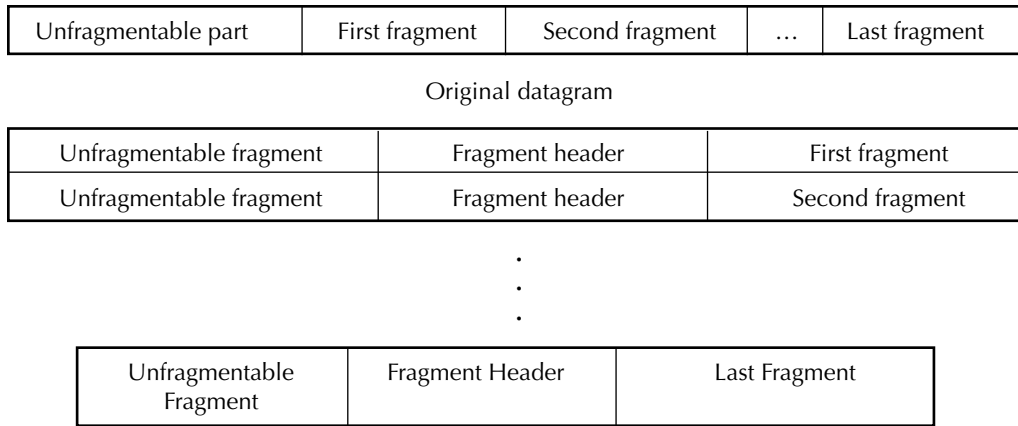

Figure 18: Large datagram and its corresponding fragments

Figure 19: The authentication header

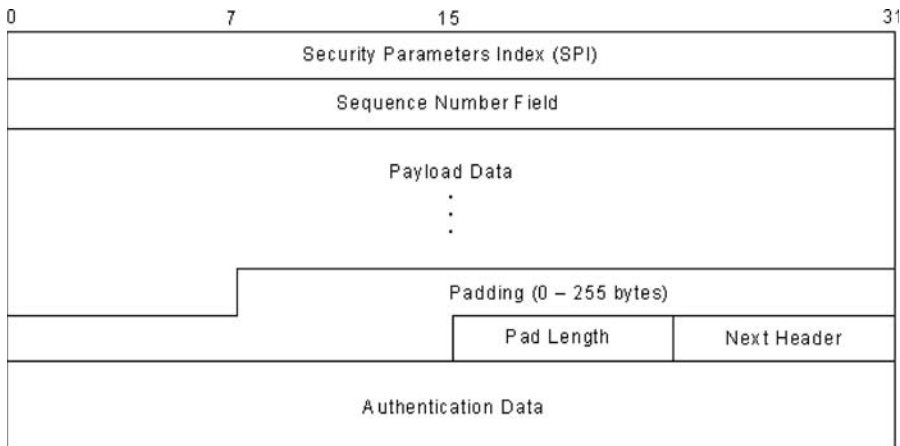

Figure 20: Encapsulating security payload header

Security parameters index (SPI) specifies the SA associated with the datagram. The SPI of value 0 is reserved for local, and values ranging from 1 to 255 are reserved by the IANA for future implementation.

The *sequence number field* is an incrementing counter that sets the antireplay. If the antireplay is activated (default case), then the sequence number is seized and should be reset for the sender and receiver.

Authentication data is a variable field of multiple eight-octet units, which describes the *integrity check value (ICV)* for the datagram through an authentication algorithm. Examples of the implemented authentication algorithms are the *data encryption standard (DES)* and *message digest (MD5)*.

Encapsulating Security Payload Header

The *encapsulating security payload header* provides confidentiality, data origin authentication, connectionless data

integrity, an optional antireplay feature, and limited traffic-flow confidentiality. The combination of offered services may vary—for example, confidentiality could be presented independently of all other services. This header can be associated with the authentication header to combine confidentiality and authentication features; this would lead to a higher degree of security and privacy (see Figure 20).

SPI, sequence number field, and authentication data are all of the same as in the authentication header. The *payload data* is a variable field of multiple eight-octet units that contains the data encapsulated within the header.

The *padding* field fills the header with nonfunctional data of size range between zero and 255 bytes presented in zeros or as random binary data based on many factors such as the implemented algorithm. The padding can be thought of as a privacy supporter that hides the actual size of the datagram and conceals a network's traffic information.

The *pad length* specifies the total size of the padding field presented in the header. The value of this field ranges from zero to 255.

Upper-Layer Header

Also known as the *pseudo header*, the *upper-layer header* has been modified to include the compulsory checksum computation over 128-bit addresses. Transport layer (upper layer) for IPv4 includes 32-bit source and destination addresses, whereas in IPv6 the structure should incorporate the 128-bit addresses of both source and destination nodes in order to execute their checksum over the TCP or UDP stream.

In IPv4, the checksum incorporated in UDP datagrams is optional. In IPv6, the checksum in the pseudo header is obligatory. IPv6 destination nodes dispose of UDP datagrams that have a zero checksum, and in turn transmit an ICMPv6 error message (see Figure 21).

The same pseudo header structure is also used for the ICMPv6 checksum. The *source address* is the 128-bit address of the sending node. The *destination address* represents the address of the final destination, even if the datagram has a routing header. The *next header* specifies the implemented link layer protocol (6 for TCP, or 17 for UDP). It might yet vary if there are extension headers that come in-between.

The *upper-layer packet length* is the size of the upper-layer header along with the data (TCP header plus TCP data or UDP header plus UDP data).

Addressing

The most obvious distinguishing part of IPv6 is its possession of much larger sizes of addresses. The size of an address in IPv6 is 128 bits, which is four times the larger than an IPv4 address. A 32-bit address space allows for 2^{32} (4,294,967,296) potential addresses, whereas IPv6 allows 2^{128} potential addresses.

The representation of addresses is also quite different from IPv4. Whereas IPv4 notates the addresses in four binary segments separated by dots, IPv6's 128-bit address is divided into 16-bit boundaries, and each 16-bit block is converted to a four-digit hexadecimal number and delimited by colons. The originated format is referred as *colon-hexadecimal*.

An example of the address format is:

00DA:04D3:0000:0000:2F 3C:02BA:0000:872D

IPv6 representation can be further simplified by removing the leading zeros within each sixteen-bit block. However, each block must have at least a single digit. Because of the suppression of the leading zero, the address becomes more simplified. Furthermore, multiple entire zero-value blocks can be compacted to only a double colon—::—and it is only done once in a single address so the number of zeros can be determined just as in the following:

DA:4D3::2F3C:2BA:0:872D

Note that the sole zero is still there; if it were compressed, then the number of zeros in the first double colon—::—and in the second would be ambiguous, so the compression should be used only once in each address to be able to identify it.

Subnetting is also supported in IPv6 addresses through subnet prefixes that exactly resemble IPv4's CIDR, where the notation is presented as address- or prefix-length just as in the following:

DA:4D3::2F3C:2BA:0:872D/64

The utilization of 128 bits for the IPv6 addresses awards superior levels of hierarchy and flexibility that eventually equip the Internet with upgraded hierarchical addressing and routing mechanisms.

Address types supported in IPv4 are also supported in the IPv6: unicast and multicast addresses.

Also, a new address type called *anycast* is supported only in IPv6; it defines an address that is allocated to multiple interfaces of usually different routers, where a datagram sent to one anycast address will be directed to the nearest interface with same address. Anycast addresses are typically assigned out of the unicast addresses. So, considering a case of a unicast address pointing to multiple interfaces, it becomes an anycast address and is no longer a unicast address. Anycast can be useful in determining the routers in a definite domain or in a subnet or determining particular routes through a certain service provider's gateways.

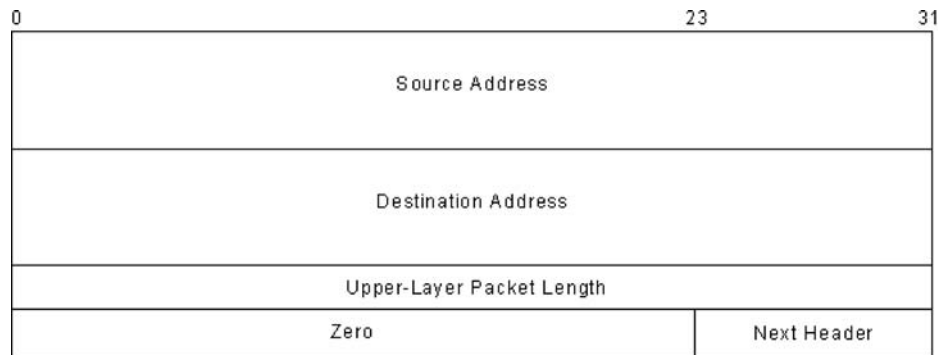

Figure 21: Upper-layer header

Summary of Features

What characterizes the IPv6 is the set of features and extensions that provide entire and enhanced network surroundings.

Larger numbers of addresses are made possible (128 bits instead of 32 bits), address configuration is made easier, and all types of datagrams can be expanded. Header format has become simpler than that specified for the older version to improve the performance and speed of datagrams processing in the network.

More enhanced options have been introduced with no restrictions and space limitations on the options in general, which creates more flexible protocol and easier adaptability to future modifications or additions.

IPv6 can be configured automatically through *plug and play*, reducing the administration and deployment overhead. Configuration can be done through DHCP server or without it by automatically configuring the use of IPv6 addresses in the link.

QOS is effectively supported by introducing the flow label field in the datagram header (labels defined for specific datagram streams), which makes QOS more applicable than in IPv4.

Authentication, confidentiality, and security options that guarantee the datagrams' integrity and privacy through the network are appended to the collection of options extensions.

Finally, efficient interoperability and backward compatibility with IPv4 is supported.

IPV4 AND IPV6 INTEROPERABILITY

Because IPv4 has been widely spread all over the globe's networks and the Internet and its address space is becoming scarce, using IPv6 becomes more attractive. It is impossible to immediately replace all deployed IPv4 addresses by IPv6, so the solution is to have them both interoperable and coexistent. *Tunneling*, *dual stacking*, and *translation* are all proposed solutions in preserving interoperability between IPv6 and IPv4.

Tunneling

To put up with IPv4 nodes, IPv6 nodes should support the entire IPv4 execution model. These types of nodes—which are supposed to be able to carry out both IPv6 and IPv4 implementation—are called *IPv6/IPv4 nodes*. IPv6/IPv4 nodes have the capability to exchange both sorts of datagrams (IPv4 and IPv6), and they can communicate straightforwardly with both IPv4 and IPv6 nodes.

Tunneling—or *IPv6-over-IPv4 tunneling*—is a way of seeking interoperability between both versions of IP. IPv6 datagrams are wrapped inside IPv4, enabling them to be transmitted through IPv4 networks and gateways.

The *encapsulating source node* (or *entry node*) prepares an IPv4 header and encapsulates the IPv6 datagram with it before transmitting it through a tunnel. When the encapsulated datagram arrives, the *decapsulating node* (or *exit node*) accepts it, eliminates the IPv4 header, and processes the IPv6 datagram. It recognizes that the encapsulated datagram is an IPv6 one by checking the protocol field; if it is equivalent to 41, then the decapsulating node

detaches and discards the IPv4 header and forwards the IPv6 datagram to the upper layer (see Figure 22).

Configured tunneling and *automatic tunneling* are two means of applying the tunneling mechanism over an inter-network. By using configured tunneling, the end-point address of the tunnel is concluded from the configuration information in the source node that encapsulates the datagram. The tunnels' end-point addresses should be stored somehow in the encapsulating node. When the node transmits the datagram via a tunnel, the destination of that datagram is determined from the tunnel's end point address itself.

Routing tables contribute to the tunneling decision, specifying whether the datagrams require tunneling or not, based on the destinations stored in these tables.

Automatic tunneling, on the other hand, has the tunnels' end-point addresses specified by the datagram itself. The tunnel extracts the 32-bit IPv4 compatible address of the destination from the datagram's header and considers it as the destination address of the datagram. If a datagram's addresses are not IPv4 compatible, then such datagrams cannot be tunneled automatically. An IPv6 address is 128 bits long; its IPv4 compatibility is determined by comparing a static routing table record of prefix value (0:0:0:0:0:0/96) with the address in the IPv6 header. If the two prefixes are similar, then the address is IPv4 compatible and the automatic tunneling is carried out. This guarantees that only IPv6 addresses that have IPv4 addresses

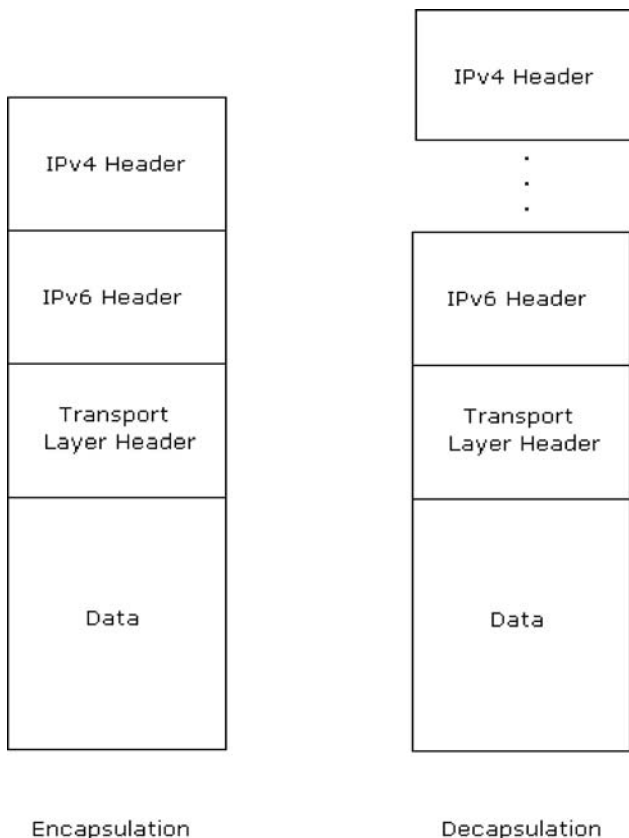

Figure 22: Encapsulation and decapsulation of IPv6 datagrams in and out of IPv4 datagrams

format in their last (low-order) 32 bits and that match this prefix criteria qualify for automatic tunneling.

Dual Stacking

The dual stack IPv6-dominant transition mechanism (DSTM) is another proposed technique to handle the interoperability between IPv4 and IPv6. It concentrates on the deployment of the new IPv6 networks and the capability to interchange datagrams with existing IPv4 networks.

DSTM applies existing protocols and does not define its own protocol or algorithm; it uses Ethernet, fiber distributed data interface (FDDI), or point-to-point protocol (PPP) in physical layers and the same protocol in upper layers that can bear both versions of datagrams (see Figure 23).

In DSTM, the address server allocates IPv4 addresses to the network nodes using certain protocols such as DHCPv6. DSTM concentrates on having IPv6 dominant, so IPv6 routing tables and mechanisms are used, which will lessen management overhead for IPv4 interoperability.

When DSTM client nodes acquire the assigned IPv4 addresses, the IPv4 datagram to be transmitted is encapsulated in an IPv6 header and transmitted through *tunnel end points* (TEPs) until it reaches a DSTM border router.

The *dynamic tunnel interface* (DTI) enables the client nodes to send an IPv4 datagram over the IPv6 TEP as well as receive IPv4 datagrams from IPv6 TEP. It is the DSTM server's responsibility to provide the TEPs for all DSTM nodes.

The border router decapsulates the encapsulated IPv4 datagram, discards the IPv6 header, and forwards the datagram to the destination node as if it is in normal IPv4 architecture.

The DSTM address pool module provides IPv4 addresses to allow DSTM clients to obtain unique IPv4 addresses. The lifetime of an address is also preserved in the pool and can be supplied to the client node along with the address.

Figure 23: Dual stack

Translating (Network Address Translation)

Network address translation (NAT) can be also used in the transition between IPv4 and IPv6. *Translation* means altering an IPv4 address to another. As for interoperability, however, the core is in either translating IPv4 addresses to IPv6 addresses, IPv6 addresses to IPv4 addresses, or both by applying *NAT protocol translation* (NAT-PT).

NAT-PT assigns IPv4 addresses to IPv6 nodes out of an address pool that contains only global unique IPv4 addresses; it then prepares sessions in which IPv6 network and IPv4 network addresses are bound and communication is thus established between the different networks. Routing throughout this whole process is transparent between both networks' end-point nodes. However, the session between both nodes that enables the sending and receiving of datagrams must maintain the same route as well as the same router.

There are two sorts of NAT-PT: traditional and bidirectional. *Traditional NAT-PT* sessions are unidirectional, only outgoing from the IPv6 network. In *bidirectional NAT-PT*, the sessions allow flow in both directions between IPv4 and IPv6 networks.

Traditional NAT-PT is also divided into two classes: *basic NAT-PT* and *NAT-PT*. The first translates the source IP address and other fields such as IP, TCP, UDP, and ICMP header checksums of IPv6 outgoing datagrams, or the destination IP address and fields in case of incoming datagrams scenario. The latter translates all those previously mentioned plus transport identifiers such as the TCP and UDP ports and the ICMP query IDs.

In bidirectional NAT-PT, the sessions across the two networks are constructed in either's node, which means that both the IPv4 and IPv6 networks' nodes are capable of initiating such connections or sessions. An IPv4 node should resolve the IPv6 network's node address via DNS in order to access it and vice versa.

INTERNET PROTOCOL SECURITY AND VIRTUAL PRIVATE NETWORKS

Internet Protocol Security

Internet protocol security (IPSec) is a security-based mechanism at the IP layer level that provides IPv4 and IPv6 with a useful set of security services. Access control, connectionless integrity, data-origin authentication, antireplay protection, encryption techniques, and traffic-flow confidentiality are all included in the IPSec services framework.

IPSec is one outcome of many applied methods involving the *authentication header* (AH), the *encapsulating security payload header* (ESP), and cryptographic key algorithms.

The implementation of such services in one's network traffic does not compromise the communication with other networks that use either different security techniques and algorithms or no security services at all for their traffic, which guarantees the interoperability between networks that implement different IPSec mechanisms.

Routers that implement an IPSec are called *security routers* or *security gateways*. Usually, IPSec operates in

hosts or security gateway networks based on defined algorithms stored in a database called a *security policy database* (SPD) and managed by the network administrator or a network application. Certain fields in datagram headers are accessed in the SPD and the relevant process for these datagrams is determined: drop them, allow them to pass, or grant them IPSec services.

Security association (SA) is the environment or connection that handles the security services accompanied by the traffic stream. It is the part that completes the whole concept of security services and IPSec, making use of AH or ESP, which are IPSec mechanisms. For a communication between two nodes, two SAs are required (one for every stream direction).

Two distinct modes are supported in SA: transport mode and tunnel mode. In the transport mode, the SA is associated between two hosts (not routers). If ESP is used, then a transport mode SA provides security services only for higher-layer protocols, not reaching the IP header or any header before the ESP header. In the case of AH, the security services reach parts of the IP header, extension headers, and some options within the IPv4 header: the IPv6 hop-by-hop options header or the IPv6 destination extension headers.

In tunnel mode, SA is provided between either two hosts—a host and a security router—or security routers. Security routers do not support the transport mode, so if any security router is on a communication edge then the incorporated SA is tunnel mode.

Two headers are used in tunnel mode SA: the outer and inner IP headers. The outer IP header relates to the IPSec processing destination (*mediatory destination*), whereas the inner IP header defines the final destination.

If AH is applied in this mode, IPSec's SA is supplied to the entire tunneled datagram along with the inner IP header and the upper-layer protocol header, as well as portions of the outer IP header mentioned in the transport mode. But if ESP is applied, then only the tunneled datagram obtains select security services. Nevertheless, ESP-based tunnel mode can be used to provide some kind of confidential traffic stream between two security routers because of the encryption of the inner IP header, which maintains the low profiles of the source and the destination. This applies to the dynamic connectivity of mobile nodes to a network in tunneled ESP SA under the protection of a firewall.

Virtual Private Networks

A *virtual private network* (VPN) is a network that links remote clients or sites with each other within a surrounding backbone via virtual gateways.

Companies and enterprises can allow their remote users, clients, employees, and any other party to access their private networks via secure virtual connections (basically, tunnels) that direct them to the Internet and the specified backbone that surrounds the VPNs, providing more simplicity and scalability instead of connecting them via heavy dedicated connections such as WANs.

To make it simple, remote entities in a network can link in a secure scalable behavior through routing to the Internet to reach their private LAN.

All of the sites in a VPN could belong to a single enterprise; in this way, a VPN is considered an intranet. If the sites belong to distinct parties, then this kind of VPN is called an *extranet*. A VPN site can be in both an intranet and one or more extranets, which means there are no restrictions in belonging to different VPNs.

Edge devices are used to configure VPNs and connectivity between sites and clients. *Provider edge* (PE) routers link to *customer edge* (CE) routers or switch at a definite data link level such as Ethernet, PPP, frame relay, and so forth. In this way, the whole connection is established to enable remote access of authorized clients to VPN sites.

Remote clients can connect to the Internet using whatever attainable connectivity method—as fast as DSL or cable or as slow as a dialup connection—and then reach the VPN server at a certain enterprise or corporate site.

To ensure a massive boundary of security handling, IPSec is applied in the surrounding backbone of a VPN to ensure authentication, privacy, encryption, and other security services offered by its core.

Other security modules and procedures include having *authentication, authorization, and accounting* (AAA) servers, symmetric and public key encryptions, and firewalls that prevent communication with unauthorized users or data. When appended, QOS features give more functionality as well as intensive reliability and throughput.

VPNs are considered valuable alternatives to network structures such as WANs and LANs. Instead of using both of these latter structures, VPN can handle connectivity no matter the geographic distance via secured, encrypted, and scalable links.

Extending geographic connectivity, improving security (through IPSec, AAA servers, etc.), improving throughput and productivity, offering global and remote connectivity and compatibility, simplifying the network topology, and saving cost and time are all advantages of VPNs.

GLOSSARY

Address resolution protocol (ARP): A protocol that maps a host's network layer address (e.g., IP address), to the hardware address (e.g., MAC address).

Anycast: A routing scheme in which the best (i.e., nearest) destination among a set of destinations will receive the packet.

Bellman-Ford algorithm: An algorithm that can figure out the shortest path between two nodes in a weighted graph, even if some of the weights are negative.

Border gateway protocol (BGP): A routing protocol that routes packets between autonomous systems. It is considered to be the core routing protocol of the Internet.

Checksum: A value that accompanies a piece of data (e.g., a packet) that helps determine whether these data have changed (i.e., corrupted) between a source and a destination. For example, a checksum may be the number of set bits in a packet.

Classless interdomain routing (CIDR): An IP addressing technique that replaced the IP address classes (A, B, C, D, and E). It allowed combining networks in supernets, reducing routing overhead.

- Datagram:** An entity of data that could be transmitted over a network. It carries information (e.g., source address, destination address) that allows it to be transmitted from a source to a node.
- Denial of service (DOS) attack:** An attack that intends to wastefully consume network resources. A DOS attack overloads a network by sending excessive traffic that the network cannot accommodate.
- Differentiated services (DiffServ):** A mechanism for assigning classes to network traffic so that certain traffic classes get precedence over other classes. For example, voice traffic—which needs low latency—may get precedence over e-mail and Web traffic. DiffServ is a QoS technique.
- Dijkstra algorithm:** An algorithm that can figure out the shortest path between two nodes in a weighted graph when the all the weights are non-negatives.
- Distance vector multicast routing protocol (DVMRP):** A protocol based on RIP for multicasting a packet over an IP network.
- Domain name system (DNS):** Allows communication with a host without knowing its hard-to-remember IP address (e.g., 141.218.143.20) by associating human-readable names (e.g. www.cs.wmich.edu) to hosts. Translating between such two addresses is done through a domain name server.
- Dynamic host configuration protocol (DHCP):** Enables a device on an IP network to request and receive an IP address from a server. It simplifies networks administration.
- Ethernet:** A local area network (LAN) architecture that uses bus or star topology. Ethernet defines standards for both the physical and data-link layers.
- Exterior gateway protocol (EGP):** A protocol used to exchange routing tables between neighboring autonomous systems.
- Forwarding equivalence class (FEC):** A group of packets are treated the same with respect to their forwarding path and how they are forwarded. Such packets exhibit similar properties.
- Host:** A device connected to a network (e.g., a computer). For TCP/IP networks, every host is identified by an IP address.
- Integrated services (IntServ):** A QoS architecture that depends on allocating required resources to deliver data before sending the actual data.
- Interior gateway protocol (IGP):** Protocol used to exchange routing information within an autonomous system.
- Internet control message protocol (ICMP):** An extension to the IP that is used to relay information such as “a datagram cannot reach its destination” and “this host is not reachable.”
- Internet protocol (IP):** A network layer protocol that facilitates exchanging packets among hosts in a network.
- Internet protocol security (IPSec):** A group of protocols that is intended to secure IP packets through encryption and authentication.
- Label-switching path (LSP):** A path within an MPLS network.
- Label-switching router (LSR):** A special router used by MPLS networks to relay labels.
- Link state advertisement (LSA):** Message sent by a router to communicate needed information for the OSPF routing protocol to work. There are five types of LSAs.
- Maximum transmission unit (MTU):** The maximum size of a packet that can be handled by a given networking device (e.g., a router).
- Multicast open shortest path first (MOSPF):** A multicast routing protocol.
- Multicast routing or multicasting:** Sending the same packet to different destinations.
- Multiprotocol label switching (MPLS):** A protocol that integrates parts of layers 2 and 3.
- Netstat:** A utility program for Windows and UNIX-based operating systems that retrieves information about current network connections and routing tables.
- Network:** Two or more computers connected together via a communications medium.
- Network address translation (NAT):** The rewriting of an IP address when a packet is going through a router or a firewall. Usually, NAT is used to protect hosts and reduce the number of IP addresses used by a network.
- Open shortest path first (OSPF):** A link-state routing protocol that depends on sending LSAs to other routers within a network.
- Payload:** Data carried by a packet.
- Point-to-point protocol (PPP):** Protocol used to establish a direct connection between two nodes in a network.
- Quality of service (QoS):** The ability to guarantee a specific level of service in terms of throughput, delay, and so on by prioritizing traffic so that more important traffic receives better service.
- Quagga:** A free routing software suite that provides implementation of many routing protocols (e.g., OSPF, RIP, and BGP).
- Resource reservation protocol-traffic engineering (RSVP/TE):** A protocol that allows resources to be reserved throughout a path for traffic.
- Routing information protocol (RIP):** The most enduring interior gateway protocol routing protocol. RIP works by sending out routing information periodically and whenever the network topology changes. When a router receives new routing information, it updates its own table.
- Simple network management protocol (SNMP):** A part of the IP protocol (application layer) that is used to manage network devices and solve network problems. It is used mainly by network administrators.
- Subnet:** Short for *subnetwork*. A network belonging to an organization can be divided into subnetworks. Typically, a subnetwork is served by a router and shares a common IP address prefix.
- Supernet:** A group of contiguous subnetworks addressed as a single subnet.
- Throughput:** The amount of data transmitted from one node to another in a given amount of time.
- Transmission control protocol (TCP):** The most commonly used transport layer protocol. It provides reliable communications over the unreliable IP protocol.

The combination of TCP and IP is referred to as *TCP/IP*.

User datagram protocol (UDP): A transport layer protocol that gives no reliability guarantees. Packets transmitted using UDP may arrive out of order or be dropped without notice.

Virtual private network (VPN): A private network owned by an organization but built from publicly available resources. For example, the Internet could be used as a communication medium for a private network. Typically, a VPN is secured via authentication and encryption.

Wireless fidelity (Wi-Fi): A set of standards and technologies that allows wireless connection to a network through an access point.

INTRODUCTION

Transport protocols are designed to deliver data to the network layer at the sender side and receive data from the same layer at the receiver's end in order to deliver it to the appropriate application protocol. Therefore, the functionality and efficiency of the transport layer determines the ability of applications to operate effectively. However, application service demands vary widely. Some—such as e-mail, HTTP, and FTP—require reliable data delivery along with a fast service; others, such as multimedia applications, may emphasize speedy transmission, even at the cost of reliability. Although the diversity of applications may imply a corresponding diversity of transport protocols, in practice two main protocols handle transmissions for a wide range of applications at the transport layer: the *transmission control protocol* (TCP) (RFC 793)* and the *user datagram protocol* (UDP) (RFC 768). The latter has been introduced as a simple protocol that allows programmers to build required functionality on top of it. The former began as a protocol with enhanced functionality that includes reliability, data sequencing, and flow control; it has evolved as a sophisticated protocol that manages congestion control and stability and also allows for fair resource allocation in dynamic and heterogeneous systems.

In both protocols, functionality is encoded in the protocol header and appears in each data packet. Therefore, each packet needs to have at least a structure appropriate for recording the process where data need to be delivered. Communication at this layer is enabled through the use of port numbers that identify each process. The 16-bit field of the packet header allows for 65,000 distinct ports; the first 1023 are reserved from application protocols such as FTP (port 21), telnet (port 23), and HTTP (port 80). That said, each receiver's application "listens" to some predetermined port; the transport layer delivers

the data to that particular port, enabling data demultiplexing at that level.

Transport layer functions, however, need to handle efficient delivery of data as well, not just demultiplex data correctly. Efficiency here involves several aspects such as ordering of packets, flow, and congestion control. Therefore, functionality has been developed for packet sequencing, receiver buffer reporting, and estimation of network dynamics, coupled with corresponding transmission strategies. The latter has been one of the major research problems at that layer because of its complexity: Balancing efficient channel utilization, fair resource allocation, and network stability in a dynamically changing environment with unknown number of flows, unknown bandwidth, and asynchronous service times was definitely not an easy task. The design target has evolved around the concept of network equilibrium, its characteristics, and convergence dynamics. That complexity did not allow for mathematically tractable optimal solutions; optimization also had to be experimentally valid.

Today, TCP is the dominant protocol for most Internet applications, whereas UDP is the protocol of choice for most real-time applications. However, new protocols have emerged today to support specific applications such as IP telephony.

We discuss the core functions of the transport layer, such as the sliding window, flow control, and congestion control along with corresponding performance metrics. We also detail the theoretical basis for the mechanisms incorporated into TCP. We then discuss various versions of TCP and present new protocols along with a prescribed framework for potential improvements. We detail the *stream control transmission protocol* (SCTP) as the designated transport protocol for telephony of IP networks, and we present the recently emerging new classes of transport protocols. We then describe the collaborative nature of the transport and network layer from the perspective of transport protocols.

*Requests for Comments can be found at www.rfc-editor.org/rfc.html

CORE FUNCTIONS AT THE TRANSPORT LAYER

The *transmission control protocol* (Postel 1981) is the dominant protocol at the transport layer. It carries more than 95 percent of the Internet traffic and allows for reliable data delivery, packet* reordering, flow, and congestion control. However, TCP functionality is not optional; that is, applications do not have the luxury of selecting only some particular set of TCP functions. Within this context, the protocol may not be appropriate for applications that intend to exploit network trade-offs. For example, multimedia applications may need to favor transmission speed at the cost of reliability or fairness at the cost of efficiency. Traditionally, the alternative choice has been the *user datagram protocol* (UDP), a protocol with almost no functionality. Indeed, UDP has only functionality for demultiplexing of data. In support of this argument, we present the protocol's header in Figure 1.

We note that even basic error detection is optional in UDP. However, the design choice of an almost-no-functionality protocol at this layer was not coincidental. A programmer may use the demultiplexing functions of the protocol (the combination of source-destination port) to deliver data to the appropriate process and incorporate the functionality of choice within the application protocols. In this way one can avoid the obligatory functions of TCP and exploit the performance trade-offs for the benefit of the application protocol. The lack of functionality is also reflected in the protocol header; its simplicity also contributes to render UDP a fast communication protocol.

On the contrary, TCP includes functionality for the following operations:

- connection establishment and termination,
- graduated consumption and detection of available bandwidth,
- reliability of transmission,
- packet ordering,
- flow control, and
- congestion avoidance and control.

We describe next the protocol functionality as it is encoded in the protocol's header. Note that the transport

Figure 1: UDP header

layer may also contribute in path *maximum transmission unit* (MTU) discovery, which traditionally belongs to the IP layer. A relevant working group exists (the PMTUD working group) that aims to specify a robust method for determining the IP maximum transmission unit supported over an end-to-end path. Various weakness in the current methods are documented in RFC 2923 and have proven to be a chronic impediment to the deployment of new technologies that alter the path MTU such as tunnels and new types of link layers.

TCP HEADER

The fields *Source Port* and *Destination Port* determine from and to whom a packet is delivered; together with *SrcIPAddress* and *DestIPAddress* of IP, they form a unique identifier. The field *Sequence Number* is used for packet reordering and also for identification of duplicate packets (see Figure 2).

Note that TCP is byte-oriented and hence the field *Sequence Number* holds the ID of the first byte of each segment. The field *Acknowledgment* allows for reporting at the receiver side; reporting is somewhat strange (for a reason): Each time a packet x is delivered, the receiver acks the $x+1$, meaning it now expects $x+1$. In addition, $x+1$ acknowledges all previously delivered packets as well; in case a previous acknowledgment has been lost, a following ack suffices for the sender to verify previous packet delivery. The aforementioned policy, called *cumulative acknowledgments*, has its cost: The receiver cannot always report precisely the concrete packet received, and it is possible for it to receive new packets out of sequence but report only the next expected packet (in fact, the first byte of the packet). The transmission strategy of TCP is therefore strictly based on the acknowledgment progress; lack of acknowledgments for consistency causes suspension of transmission as well. This policy is known as the *ack-clocking* mechanism of TCP. The field *HdrL* refers to a segment's header length in units of thirty-two bits and is necessary because of the optional nature of some fields, which results in unknown header length. The header also allows for six distinct *flags*:

- *syn*, *fin*, which are used in connection establishment, and termination;
- *reset*, which is used when unexpected data are received;
- *push*, which signifies urgent data delivery;

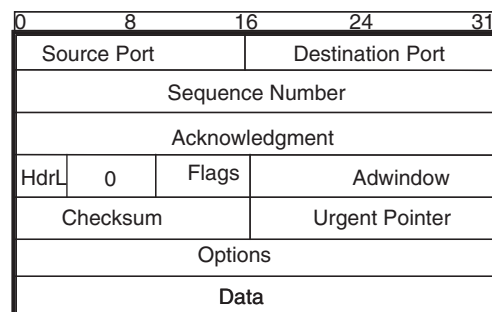

Figure 2: TCP header

*TCP's terminology for packet is *segment*. We use both terms throughout this text.

- *urgent pointer*, which indicates use of the urgent pointer; and
- *ack*, which reports acknowledgments.

The fields *SYN* and *ACK* are used during connection establishment, which is implemented using a three-way handshake algorithm. The sender initiates a connection request by marking the *syn* flag of the TCP header and assigns a random sequence number x (see Figure 3). The receiver responds by also marking the *syn* flag and assigns a sequence number y . In the same response, the receiver marks the acknowledgment field with the $x+1$ number, which means that the receiver now waits for the segment with a sequence of bytes starting from $x+1$. The sender acknowledges the response of the receiver similarly—that is, it marks the acknowledgment field with $y+1$ and enters the establishment phase. As soon as the acknowledgment arrives at the receiver, the connection is established.

The order of events may differ occasionally. For example, the sender and the receiver may request connection establishment simultaneously or some request or acknowledgment may be lost. In any case, an establishment phase is confirmed when both the sender and the receiver

have issued one *syn* request and received one corresponding *ack* for their request.

The field *Adwindow* (for *advertised window*) is where buffer space is reported and is used for flow control. The field *Checksum* is used for error detection. Finally, options are possible: The field *Options* has been widely used not only for evaluating new versions but also for enhancing the functionality of existing versions through the use of time stamps and so on.

Now consider that the sender starts transmitting segments from this window. If *acks* do not arrive, then transmission is suspended. By default, retransmission is triggered by time-outs (although more sophisticated ways have also been deployed). Therefore, reliability requires:

- acknowledgments;
- buffers at both the sender and the receiver to hold packets in flight and out of order, respectively;
- time-out to trigger retransmission; and
- sequence numbers to allow for distinction of duplicate packets and ordering.

As shown in the sliding window operation of Figure 4, the sender maintains pointers that determine the transmission window, based largely on the pace of *acks*. For example, given the limitation of buffer space, which restricts sending to the amount of

Last byte written – Last byte acked

the lack of new *acks* does not allow the pointer *last byte acked* to move forward, resulting in suspended transmission. The pointers at the receiving end allow for *flow control*: The receiver reports the amount

$$\text{Adwindow} = \text{MaxRcvBuffer} - (\text{LastByteRcvd} - \text{Last ByteRead}) \quad (1)$$

to the sender, which incorporates the pace at which the receiving application reads data from the buffer and, in turn, determines the

$$\text{EffectiveWindow} = \text{AdWindow} - \text{Data_in_flight} \quad (2)$$

Figure 3: Three-way handshake

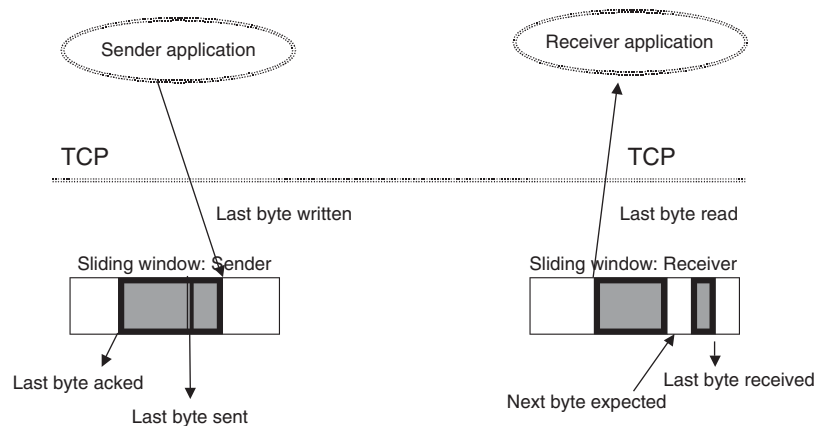

Figure 4: Sliding window operation

where

$$\text{Data_in_flight} = (\text{LastByteSent} - \text{LastByteAcked}) \quad (3)$$

Obviously,

$$\text{LastByteWritten} - \text{LastByteAcked} \leq \text{MaxSendBuffer} \quad (4)$$

Retransmission

Retransmission in TCP is triggered by either a time-out event or a *three-duplicate acknowledgment* (3-DACK). In the event of a segment loss, the delivery of consequent segments triggers *duplicate acks* (dacks). Three such dacks indicate the loss of a segment, and retransmission is then initiated. Because the delivery of out-of-order segments is possible, a single dack does not suffice to convince the sender that the segment is lost; three dacks are more convincing. In the event of persistent congestion, more segments may be lost. In that case, dacks may not be generated and the sender will thus time-out. The time-out will trigger retransmission as well. We describe in more detail in the section on congestion control the different retransmission policies of various TCP versions that correspond to time-out or three-dack events, respectively.

Time-Out

The retransmission time-out policy of standard TCP is governed by the rules of RFC 2988. Most existing TCP versions implement that standard. The algorithm is based solely on *round-trip time* (RTT) measurements in an effort to capture dynamic network conditions by measuring the variation of the RTT samples. In particular, the *retransmission time-out* (RTO) is calculated upon each ack arrival after smoothing out the measured samples and weighting the recent history. In this way, the time-out reflects the weighted average delay currently in the network rather than the instantaneous network delay. Furthermore, the time-out takes into account the RTT variation measured during the previous transmission rounds. More precisely, upon each ack arrival, the sender updates the RTT variation:

$$\begin{aligned} \text{RTTVAR} &= \frac{3}{4} \times \text{RTTVAR} + \frac{1}{4} \\ &\quad \times |\text{SRTT} - \text{RTT_sample}| \end{aligned} \quad (5)$$

This smooths the expected RTT before calculating the retransmission time-out:

$$\text{SRTT} = \frac{7}{8} \times \text{SRTT} + \frac{1}{8} \times \text{RTT_sample} \quad (6)$$

Finally, it calculates the retransmission time-out value,

$$\text{RTO} = \text{SRTT} + \max(G, 4 \times \text{RTTVAR}) \quad (7)$$

where RTTVAR holds the RTT variation and SRTT the smoothed RTT. G denotes the timer granularity, which is incorporated in order to assign a lower bound for the retransmission time-out to protect it against spurious time-outs (Sarolahti and Kojo 2003) (i.e., when RTT equals the timer granularity).

Zhang (1986) identifies several drawbacks of the TCP retransmission timer, reports its intrinsic limitations, and concludes that mainly external events should trigger retransmissions; timers should be used only as a last notification of packet loss. The Eifel algorithm (Ludwig and Gurtov 2005; Ludwig and Meyer 2003) focuses on spurious time-outs. A *spurious time-out* happens in case of a sudden delay spike on the link, where the round-trip delay exceeds the expected value calculated for the retransmission time-out. As a result, all data in flight are falsely considered lost and are being retransmitted. The Eifel algorithm uses the TCP time-stamp option to detect spurious timer expirations. Once a spurious time-out is detected, the sender does not back off, but instead restores the transmission rate to the recorded rate before the time-out event. The *forward RTO algorithm* (F-RTO) (Sarolahti and Kojo 2003) targets the detection of spurious time-outs, too. Instead of using time-stamp options, the algorithm checks the ack packets that arrive at the sender after the timer's expiration. F-RTO observes whether the acks advance the sequence number, concludes whether the time-out was spurious, and determines the appropriate recovery policy accordingly.

Both of the above algorithms (Eifel and forward RTO) are currently in the standardization process of the Internet Engineering Task Force. Both algorithms consider outstanding data packets only after the timer expires, although the nature of the problem also calls for design modifications of the time-out itself. Recently, Chandrayana et al. (2006) investigated the problem of TCP flow synchronization, too, and identified anomalies in TCP's transmission policy. More precisely, they report TCP performance problems in terms of fairness (i.e., TCP treats unfairly flows with long RTTs) and window synchronization. They attempt to break flow synchronization by randomizing the sending times in TCP. Psaras, Tsaoussidis, and Mamatas (2005) have shown that time-out adjustments, based solely on RTT estimations, do not correspond to the level of flow contention. The authors investigated the behavior of TCP in high-contention scenarios and confirmed that it is possible for the time-out to decrease while contention increases. The authors conclude that this anomaly is the result of flow synchronization.

CONGESTION CONTROL

A network is considered congested when too many packets try to access the same router's buffer, resulting in packets being dropped. In this state, the load exceeds the combined network and buffer capacity. During congestion, actions need to be taken by both the transmission protocols and the network routers not only to avoid a congestive collapse but also to ensure network stability, high throughput, and fair resource allocation to network users. Indeed, during a collapse, only a fraction of the existing bandwidth is utilized by traffic that finally reaches the receiver.

The sender maintains a *congestion window* (cwnd) to record the amount of data the network can hold, an approach similar to the Adwindow and the receiver. Then the sender needs to calculate the *sending window* as the minimum of the two windows [i.e., $\min(\text{adwindow},$

cwnd)] minus the *data in flight*. This way, both the receiver and network overflow can be avoided (Floyd 2000; Jacobson 1988).

The real issue, however, is how to assign values to congestion windows that correspond to current network dynamics. Unlike the receiver's buffer, for which the receiver can report accurate measurements of free space to the sender, the network state cannot be reported for two reasons: (1) Network and transport protocols differ, hence extra mechanisms are required for cross-layer communication; and (2) whatever network buffer capacity may be reported to the sender cannot be trusted because flows may write there anytime. Therefore, it appears reasonable to seek a way to estimate the overall network state or monitor the network dynamics rather than calculate precise capacities. However, monitoring the dynamics is half the story. What remains unknown is the level of flow contention; even if each flow knew the available network buffer capacity, the value of the congestion window cannot be determined because bandwidth sharing requires knowledge of the *fair share* as well. Congestion control therefore requires window adjustments in a manner that the system of flows will converge to some equilibrium where resources are well utilized and sharing is possible. How can we adjust the congestion window to guarantee both efficiency and fairness? We address this issue in the following sections.

PERFORMANCE METRICS

Several metrics have been proposed and used for evaluating various performance aspects at the transport layer. Because of the several performance trade-offs at this layer, it becomes difficult to capture a protocol's behavior by a single metric. Indeed, new performance aspects require new metrics. For example, the contribution of a protocol's transmission policy to energy consumption requires a new metric; energy expenditure cannot capture the particular contribution of this layer alone.

A major task of the protocols at this layer is to regulate traffic in a manner that allows for the efficient utilization of resources (i.e., bandwidth) and fair allocation to participating users. That said, metrics characterize system performance as well as user's application efficiency. For example, although a system may appear as highly efficient in bandwidth utilization, there might be users that do not really experience that performance had the allocation of bandwidth not been fair. From another perspective, utilization itself is not the whole story, because bandwidth may be consumed by headers, retransmissions, and control packets. Therefore, utilization and efficiency have to be occasionally distinguished. Network utilization is usually captured by *throughput*, which is defined as:

$$\text{Throughput} = \text{Data transmitted} / \text{Connection time} \quad (8)$$

The metric *goodput* is widely used to capture the application efficiency instead of the network utilization scores. The goodput for each flow is defined as:

$$\text{Goodput} = \text{Original data} / \text{Connection time} \quad (9)$$

where original data is the number of bytes delivered to the high-level protocol at the receiver (i.e., excluding retransmitted packets) and connection time is the amount of time required for the corresponding data delivery. Because goodput is an average rate and as such cannot capture the fluctuations in time, the metric can be further extended in accordance with Zhang and Tsoussidis (2001). The *allotted system goodput* (ASG), for example, can be defined as the system goodput within a short sampling period (usually at a timescale of several RTTs) and could be used to capture the particularity of protocol behavior over time in dynamically changing environments.

The protocol efficiency can also be studied from another perspective. *Overhead* can be used as a metric to realize the protocol transmission effort to complete reliable data delivery:

$$\text{Overhead} = (\text{Bytes sent} - \text{original bytes}) / \text{Bytes sent} \quad (10)$$

where *bytes sent* is the total bytes transmitted by TCP senders and *original bytes* is the number of bytes delivered to the higher level protocol by all receivers, excluding retransmitted packets and TCP header bytes. This metric captures the portion of consumed bandwidth, or the percentage of the transmitted data, that is wasted on packet retransmissions and protocol header overhead. Similar metrics may also be derived to capture the protocol effort as the amount of unexploited available resources or even the protocol's energy saving potential (see Mamatas and Tsoussidis 2006 for more details).

Fairness is a common metric and is measured by the *fairness index*, which is defined in Bakre and Badrinath (1995) as:

$$\text{FairnessIndex} = \frac{\left(\sum_{i=1}^n \text{throughput}_i \right)^2}{n \sum_{i=1}^n \text{throughput}_i^2} \quad (11)$$

where throughput_i is the throughput of the i th flow measured at a timescale of connection time. Similarly, *allotted fairness* can be defined as the corresponding fairness within a short sampling period; it is used to capture the system fairness over time under dynamic traffic loads. *Allotted throughput* can also be used to compute the *short-term fairness*, which is derived from the traditional fairness index:

$$\text{ShortTermFairness} = E_t \left[\frac{\left(\sum_{i=1}^n \text{throughput}(t)_i \right)^2}{n \sum_{i=1}^n \text{throughput}(t)_i^2} \right] \quad (12)$$

where, $E_t[\cdot]$ denotes the computation of the mean along the time, and $\text{throughput}(t)_i$ is allotted throughput of the i th flow over time t .

To investigate the performance smoothness observed by end users (i.e., transmission gaps), the allotted throughput of individual flows $throughput(t)_i$ can be used to observe the performance fluctuations. In this context, *coefficient of variation* (COV) (see Yang and Lam 2000; Zhang and Tsoussidis 2001) can be used to gauge the throughput smoothness experienced by flow i :

$$CoV_i = \frac{\sqrt{E_i\{throughput_i^2(t) - E_i\{throughput_i(t)\}^2}}{E_i\{throughput_i(t)\}} \quad (13)$$

For a system with multiple flows, the system COV is the average of COVs of all flows.

NETWORK AS A BLACK BOX

If we consider the network as a *black box* that only provides binary feedback to network flows upon congestion, all of the control burden is shifted to end users. Regardless of the network particularity or the current network state, the algorithm will react similarly in all cases because no further information is available to end users. However, the goal of each sender is to operate independently but nevertheless to adjust its rate (or window) in a manner that the total bandwidth of the network will be expended fairly and effectively. From its algorithmic perspective, the above problem is challenging because the distributed entities (sources) neither have any prior or current knowledge of the other entities' states nor know the system's capacity and the number of competitors. Hence, the goal of fairness and efficiency appears initially difficult to attain. However, if the system is entitled to a prescribed behavior and the entities agree on common transmission tactics, then convergence* to fairness becomes feasible (Lahanas and Tsoussidis 2003 "Exploiting"). *Additive increase, multiplicative decrease* (AIMD) (Chiu and Jain 1989), the traditional congestion control algorithm of the Internet, operates within that scope: It increases additively the rate of the senders (by a value α) until the system reaches congestion. Upon congestion, all senders decrease their rate multiplicatively using a decrease ratio, β .

The goals we set for congestion avoidance and control are to:

- achieve high bandwidth utilization,
- converge to fairness more quickly,
- minimize the length of oscillations, and
- maintain high responsiveness.

Although the sources may discover their fair share early on, the dynamics of real systems in practice prohibit a straightforward adjustment; instead, they call for continuous oscillations as a means of discovering the available bandwidth. *Smoothness* is reflected by the magnitude of the oscillations during multiplicative decrease. *Responsiveness* is measured by the number of steps (or RTTs) to reach an equilibrium (i.e., to equate the windows in order to be in a fair state).

*Convergence to fairness should be perceived as the procedure that enables different flows that consume different amount of resources each to balance their resource usage.

Figure 5: Synchronous control system model of n users sharing a network (Chiu and Jain 1989)

A synchronous-feedback control system model is shown in Figure 5. In congestion control, the load change is the response in one occurrence. This event is a binary feedback. The synchronous model is characterized by a synchronous generation of responses in congruity with Chiu and Jain (1989). The system response is 1 when bandwidth is available and 0 when bandwidth is exhausted. The instruction to the system entities (sources) is to increase or decrease their data rate, respectively. Note that, in real networks, the responsive behavior of the system is not administered by any centralized authority with additional knowledge of the network dynamics, it is simply a packet drop because of congestion that naturally happens when bandwidth is exceeded.

The system has n users (flows), and the instantaneous throughput for the flow i is X_i . The system's goal is to operate at an optimal point X_{goal} . Note that this point is not necessarily bandwidth B because throughput might decrease before we reach B . We assume that responses are synchronous and consequently the duration of RTTs is common for all flows. Hence, the sources respond uniformly by decreasing their windows in response to a 0 signal; they increase their windows by one in response to a signal of 1 (in the case of classical AIMD). The limitations of the system are derived from these dynamics of packet networks:

- Bandwidth B is limited,
- each flow is not aware of the throughput rates (window sizes) of other flows,
- each flow is not aware of the number of competitors in the channel, and
- no flow is aware of the size of bandwidth B .

Multiplicative decrease guarantees that different window sizes will gradually equate because the gap between the windows is gradually reduced. The decrease ratio determines the length of oscillation, which reflects the convergence speed as well, however, at the cost of smoothness. Figure 6 depicts the graduated adjustments of the windows of two users. After each multiplicative decrease (e.g., halving the window in TCP) the gap between the two user windows is reduced and the total resources used approach the line where user demand is equal. Although both users increase their windows, the gap remains constant but the resource utilization approaches the line Total demand = C .

Although the synchronous model is widely adopted, it is associated with a number of assumptions or

Figure 6: AIMD dynamics described in Chiu and Jain (1989)

simplifications that may not really hold in real networks. We note that some drawbacks of the simplified synchronous model are somewhat canceled experimentally because of the wide use of long FTP flows. In a recent work, Lahanas and Tsoussidis ("t-AIMD" 2003) described an asynchronous-feedback model that corresponds to the diverse round-trip times (RTTs) of competing flows within the same communication channel. In this system, authors show that congestion epoch, which equals the RTT of a flow times the number of additive increases, is common knowledge among all competing flows. Based on this knowledge, they proposed a new algorithm that increases the consumption rate proportionally to the RTT of the flow using a mechanism that adjusts the sizes of the windows of the competing flows at the end of each congestion epoch. Long RTT flows are relatively favored because their window is increased more quickly than in a traditional AIMD scheme. The system reaches a window-based equilibrium. This mechanism, named τ -AIMD, introduces an extra adaptive component τ to the additive increase formula of AIMD.

In two papers, Yang, Kim, and Lam (2001) and Yang and Lam (2000) compare AIMD and *multiplicative additive increase, multiplicative decrease* (MAIMD) and introduce general AIMD. They show that the convergence speeds of AIMD and MAIMD are similar. Furthermore, MAIMD has some advantages; for example, its speed to use available network bandwidth can be much faster than AIMD. Authors have made their investigations using an asynchronous system model in which users can have different round-trip times.

Incorporating the Additive Increase, Multiplicative Decrease Algorithm into TCP

Standard TCP applies graduated multiplicative and additive adjustments to the sender's congestion window in order to guarantee stability and fairness to other flows that possibly attempt to simultaneously utilize the channel's bandwidth. The additive increase multiplicative decrease (AIMD) algorithm is used to implement TCP window adjustments. Based on the analysis of Chiu and Jain, the algorithm achieves stability and converges to fairness

in situations where the demand (of competing flows) exceeds the channel's bandwidth. Tahoe, Reno, and SACK are the three most common reference implementations of TCP. They rely on lost segments to detect congestion so that a flow can adjust its rate to its available share. We discuss each version in turn.

TCP Tahoe congestion control algorithm includes *slow start*, *congestion avoidance*, and *fast retransmit* mechanisms (Allman, Paxson, and Stevens 1999; Postel 1981). It also implements an RTT-based estimation of the retransmission time-out. In slow start, the sender increases its window size by one segment each time an acknowledgment is received until it reaches the *slow start threshold* (SSTHRESH). From that point onward, it increases the window by one segment each time a *full window* of acknowledgments is received (*congestion avoidance* phase). In the *fast retransmit* mechanism, a number of successive dacks (the threshold is usually set at three) that are carrying the same sequence number triggers a retransmission without waiting for the associated time-out event to occur. Note that the slow start threshold is halved whenever a congestion event is detected; the threshold is then increased in accordance with the congestion window.

TCP Reno introduces *fast recovery* in conjunction with *fast retransmit*. The idea behind fast recovery is that a dack is an indication of available channel bandwidth because a segment has been successfully delivered. This, in turn, implies that the congestion window (cwnd) should actually be incremented upon a dack delivery. In particular, receiving the threshold number of dacks triggers fast recovery: The sender retransmits one segment and sets the congestion threshold to half the current cwnd. Then, instead of entering slow start as in Tahoe, the sender increases its current cwnd by the predetermined threshold number. The fast recovery stage is completed when an acknowledgement for new data is received.

Although Reno significantly improves the behavior of Tahoe TCP when a single packet is dropped from a window of data, it degrades performance when multiple packets are dropped. A modification of Reno, named *New Reno* (Floyd and Handley 1999), changes the sender's behavior during fast recovery and reduces Reno's time-outs in case of multiple packet drops. New Reno remains in fast recovery until all of the data (which it has initiated during fast recovery) have been acknowledged. TCP SACK (Mathis et al. 1996) adds *selective acknowledgments* (sacks) and *selective repeat* to TCP. A comparative evaluation of the aforementioned versions can be found in Fall and Floyd (1996).

AIMD Fast Convergence

A recent improvement to AIMD—*additive increase, multiplicative decrease with fast convergence* (AIMD-FC)—was proposed in Lahanas and Tsoussidis ("Exploiting" 2003). AIMD-FC positively affects efficiency and fairness. It is not based on a new algorithm but on an optimization of AIMD during the convergence procedure that enables the algorithm to converge more quickly and achieve higher efficiency. AIMD-FC increases the bandwidth utilization of AIMD from 3/4 to 5/6.

AIMD-FC departs from AIMD and the following four observations:

1. During the additive increase phase, an equal amount of system resources is allocated to each flow. This amount (k) is public or common knowledge (i.e., it is known to every flow in the system).
2. AIMD affects both the initial windows and the amount of system resources (k), that has been fairly allocated during the multiplicative decrease phase. Note that the manipulation of the initial (and unknown) windows is the real target for achieving fairness.
3. The average distance of actual utilization from the capacity line (see Figure 6) when the system is in equilibrium depends only on the multiplicative decrease factor (Chiu and Jain 1989).
4. Two algorithms may need the same number of cycles to converge to fairness—for example, two variants of AIMD with different additive increase rate but the same multiplicative decrease ratio. The number of increase steps determines the relative efficiency of the algorithm to converge to fairness.

Practically, fairness is achieved in AIMD-FC by releasing (through multiplicative adjustments of the windows) the initial resources of the flows (which are unknown to other flows) because, during the additive increase phase, the flows increase their resource consumption uniformly. So, it is becoming apparent that the distinctive difference of AIMD and AIMD-FC concerns the portion of the congestion window that is affected by multiplicative decrease (this portion is called *decrease window*).

MEASUREMENT-BASED CONGESTION CONTROL

One can measure network conditions, estimate the available bandwidth or even flow contention, and obtain some knowledge about the network. However, measurements are taken at time instances that may not necessarily represent current network dynamics or may not correspond to the overall conditions. As a consequence, protocols may not manage to accurately estimate the load and predict its duration, resulting in either wrong estimations or wrong recovery strategies. Furthermore, some generic questions cannot really be addressed with certainty: How frequently should we measure the network? How far can we trust our measurements? How responsive should the recovery strategy be? How shall we associate the instantaneous measurements of congestion with the network load over some sufficiently long but also sufficiently recent time period? That said, the network may not be a black box, but it is certainly not better than *gray*, occasionally involving a considerable risk.

TCP Vegas

A well-designed, measurement-based congestion avoidance mechanism is TCP Vegas (Brakmo and Peterson 1995). Vegas defines *base RTT* to be the *minimum of all measured RTTs* and *expected rate* to be the *ratio of the congestion window to base RTT*. The sender measures the

actual rate based on the sample RTTs. If the difference between the expected rate and actual rate is below a lower bound, then the congestion window increases linearly during the next RTT. If the difference exceeds an upper bound, then TCP Vegas decreases the congestion window linearly during the next RTT. According to Brakmo and Peterson (1995), Vegas achieves better transmission rates than Reno and Tahoe.

TCP Real

TCP Real (Tsaoussidis and Zhang 2002; Zhang and Tsaoussidis 2001) employs a receiver-oriented and measurement-based congestion control mechanism that significantly improves TCP performance over heterogeneous (wired and wireless) networks and over asymmetric paths. TCP Real goes beyond the limitation of ack-based binary feedback. It estimates the level of contention and distinguishes the reason of packet losses. TCP Real relies on the following:

- *receiver-oriented congestion detection*, which abrogates the impact of false assessments at the sender because of lost or delayed acknowledgments on a lossy reverse path (the receiver measures the network condition and attaches the results to the acks sent back to the sender); and
- *measurements*, which are based on wave patterns that distinguish the nature of a packet loss because of congestion or transient wireless errors.

A *wave* (originally introduced in Tsaoussidis, Badr, and Verma 1999) consists of a number of fixed-sized data segments sent back-to-back, matching the inherent characteristic of TCP to send packets back-to-back. The receiver computes the data-receiving rate of a wave, which reflects the level of contention at the bottleneck link. If a packet drop results from a wireless error, then the data-receiving rate will not be affected by the gap of missing packets because the wave size is published to the receiver. The congestion window is multiplicatively reduced only when a drop is associated with congestion.

TCP Westwood

In TCP Westwood (Casetti et al. 2001; Mascolo et al. 2001), the sender continuously measures the rate of the connection by monitoring the rate of returning acks. Upon three duplicate acknowledgments or a time-out, the slow start threshold and the congestion window are set to be consistent with the effective bandwidth used at the time the packet loss is experienced. No specific mechanism exists to support error classification and the corresponding recovery tactics for wired or wireless networks, albeit the proposed mechanism appears to be effective over symmetric wireless links because of its efficient congestion control.

One can go beyond the blind algorithms or the high risk of estimations and actually ask the network for help. Of course, precision comes at some cost. Besides the practical difficulty of layer collaboration and the issue of convincing people to add functionality (and invest money) to their network, the issue of recovery strategies remains. In other words, even when the network is really a *green* box (which

practically is extremely difficult), changes may be so rapid and unpredictable that our costly and painful effort to obtain some information may go wasted. An approach to calculate the fair share without any network support was published in Attie, Lahanas, and Tsaoussidis (2003).

Bimodal Mechanism

Bimodal congestion avoidance and control mechanism (Attie, Lahanas, and Tsaoussidis 2003) measures the fair share of the total bandwidth that should be allocated for each flow at any point during the system's execution. If the fair share were known, then the sources could avoid congestion by adjusting immediately after the fair share was discovered to a new state in which the bandwidth allocation of each flow is exactly its fair share. However, bandwidth availability not only is a matter of channel capacity but also is dependent on the number of participating flows and the transmitting behavior of the sources. So, fair share can be measured only in an equilibrium state. The authors proposed a *bimodal mechanism*, which is based on the idea that upward and downward adjustments need to operate in association with the system state. Action is determined based on whether the system is in equilibrium (fair share is known) or not (fair share is unknown).

When the fair share is unknown, the algorithm behaves like AIMD until two congestion cycles have passed, which suffices to recalculate the fair share. The algorithm then sets the bandwidth allocation for flow f to ϵ (where ϵ is a small tunable parameter) times the calculated fair share and shifts to *known fair share* mode. So, bimodal congestion control algorithm explicitly calculates the fair share and converges in two congestion cycles to the fair share. In this mode, the algorithm continues to use additive increase and multiplicative decrease, but the multiplicative decrease factor is ϵ instead of β . This algorithm calculates fair share explicitly, and so fairness is not compromised in this approach. Furthermore, because this algorithm restricts its flows to use only their fair share, it can be used in conjunction with any other transport protocol (e.g., standard AIMD-based protocols) without monopolizing for itself most of the available bandwidth. This is in contrast with the TCP-friendly protocols, which attempt to grab available bandwidth. Of course, this algorithm will not work well in conjunction with other protocols that aggressively (and unfairly) grab a disproportionate share of the bandwidth for their flows.

FRAMEWORK FOR POTENTIAL IMPROVEMENTS

The application requirements and the limitations of congestion control circumscribe a framework for potential improvements. We identify five distinct cases of interest that have been discussed in the recent literature (see Tsaoussidis and Matta 2002).

Additive increase leads naturally to congestion, which, in turn, degrades throughput for two reasons:

1. Routers need time to recover even from a transitory congestive collapse and sources need time to detect and retransmit missing packets (Fall and Floyd 1996).

2. Congestion control is triggered upon congestion; the window is adjusted backward and the time-out is extended, which in turn degrades the protocol's capability to detect and exploit error-free conditions and bandwidth availability, respectively.

Additive increase is not efficient when the network dynamics encompass rapid changes of bandwidth availability. For example, when short flows that cause congestion complete their task, bandwidth becomes available. Similarly, when a hand-off is completed in a cellular network, the entire channel's bandwidth becomes available. A more rapid response is then clearly indicated (Tsaoussidis and Matta 2002).

Multiplicative decrease causes transmission gaps that hurt the performance of real-time applications that experience jitter and degraded goodput. Furthermore, multiplicative decrease with a factor of one-half or a window adjustment to two packets characterizes a rather conservative strategy.

Error detection lacks an appropriate classification module that would permit a responsive strategy oriented by the nature of potential errors. In other words, when errors appear to be transient because of short-lived flows or random wireless interference, congestion control mechanisms (i.e., time-out extension and multiplicative window adjustment) are triggered unduly. The insufficient error detection and classification may also lead to unfair bandwidth allocation in mixed wired and wireless networks. By default, flows that experience wireless errors do not balance their bandwidth loss with a more aggressive recovery, although such behavior could be justified: Flows that experienced no losses have occupied extra bandwidth at the router temporarily when the wireless errors forced some senders to back off.

A source-based decision on the transmission rate, based on the pace of the acknowledgments, necessarily incorporates the potentially asymmetric characteristics (e.g., ack delays or losses) of the reverse path (Balakrishnan, Padmanabhan, and Katz 1997). Hence, the sender's transmission rate does not always reflect the capacity of the forward path. This situation has a direct effect on efficiency because available bandwidth remains unexploited.

Several proposals have been presented to tackle the problems of TCP over wireless and mobile networks. Most of these proposals rely on some form of local retransmission at the wired and wireless border (e.g., Bakre and Badrinath 1995; Balakrishnan et al. 1995; Goff et al. 2000). Some recent protocols restrict the modifications at the transport level (see also Papadimitriou and Tsaoussidis, "Transport Layer" 2006). *Freeze TCP* (Goff et al. 2000) distinguishes hand-offs from congestion through the use of the advertised window. WTCP (Sinha et al. 1999) implements a rate-based congestion control replacing entirely the ack-clocking mechanism. *TCP probing* (Tsaoussidis and Badr 2000) grafts a *probing cycle* and an *immediate recovery* strategy into standard TCP in order to control effectively the throughput and overhead trade-off. Although TCP probing deals effectively with both throughput and energy performance in heterogeneous networks because of its probing mechanism, it may not satisfy the requirements of delay-sensitive applications for reduced

transmission gaps. TCP Westwood (Casetti et al. 2001; Mascolo et al.; Wang 2001) relies on bandwidth estimation to set the slow start threshold and the congestion window on three duplicate acknowledgments or a timeout. No specific mechanism exists to support error classification and the corresponding recovery tactics for wired and wireless networks, albeit the proposed mechanism appears to be relatively effective over symmetric wireless links because of its efficient congestion control. Naturally, a sender-based strategy does not cancel the TCP deficiency over asymmetric channels.

TCP-FRIENDLY PROTOCOLS

A new family of protocols has recently emerged, namely the *TCP-friendly protocols* (Floyd, Handley, and Padhye 2000; Floyd Handley, Padhye, and Widmer 2000; Handley et al. 2001; Feng, et al. 1997). Congestion control was designed based on two fundamental requirements: (1) to achieve smooth window adjustments, which is done by reducing the window decrease factor during congestion; and (2) to compete fairly with TCP flows, which is achieved by adjusting the increase rate calculated from a TCP throughput equation. *TCP-friendly rate control* (TFRC) (Handley et al. 2001) is an equation-based TCP-friendly congestion control protocol. The sender explicitly adjusts its sending rate as a function of the measured rate of loss events to compete fairly with TCP. A loss event consists of one or more packet drops within a single round-trip time. The receiver calculates the loss event rate and reports feedback to the sender. The benefit of TFRC is its “gentle” rate regression upon congestion. *General additive increase, multiplicative decrease* (GAIMD) Yang and Lam (2000) generalizes TCP by parameterizing the congestion window increase value α and decrease ratio β . It provides a balancing relationship between α and β to guarantee friendliness:

$$\alpha = 4(1 - \beta^2)/3 \quad (14)$$

Originally departing from the model of Padhye et al. (2000) and based on experiments, Yang and Lam (2000) have chosen $\beta = 7/8$ as the appropriate value* for the reduced window (i.e., less rapidly than TCP does). For $\beta = 7/8$, (1) gives an increasing value $\alpha = 0.31$.

Obviously, the choice of parameters α and β directly affects the “responsiveness” of the protocols to conditions of increasing contention or bandwidth availability. Indeed, the combined dynamics of α and β from equation 1 exploit an interesting trade-off: A choice of α that allows for rapid bandwidth consumption (additive increase) is counterbalanced by a friendliness-driven response with multiplicative decrease, rendering the protocol inappropriate for real-time applications.

The differences between TCP, TFRC,** and GAIMD congestion control lie mainly in the specific values of α and β . Their similarities lie in their AIMD-based congestion

control, a characteristic that enables us to include them both in the family of TCP (α , β) protocols. Standard TCP is therefore viewed here as a specific case of TCP (α , β) with $\alpha = 1$, $\beta = 0.5$. From our perspective, TCP-friendly protocols are designed to satisfy specific application requirements; however, as it was shown in Tsoussidis and Zhang (2005), they may exhibit further weakness when bandwidth becomes available rapidly. Apparently, the trade-off between responsiveness and smoothness can be controlled to favor some applications, but it will cause other damages. Considering the variability of network conditions and the duration of flows, the equation-based recovery may provide weak guarantees for friendliness.

Rate adaptation protocol (RAP) (Rejaie, Handley, and Estrin 1999) is a rated-based protocol that employs an AIMD algorithm for the transmission of real-time streams. The sending rate is continuously adjusted by RAP in a TCP-friendly fashion by using feedback from the receiver. The protocol uses layered encoding and the associated component—namely, *layer manager*—tries to deliver the maximum number of layers that can fit in the available bandwidth. Rate adaptation is performed on a timescale of round-trip times, but layers are added and dropped on a longer timescale. However, because RAP fully complies to AIMD, it causes short-term rate oscillations, mainly because of multiplicative decrease. Furthermore, RAP occasionally does not result in interprotocol fairness.

Datagram congestion control protocol (DCCP) (Kohler, Handley, and Floyd 2003) is a new transport protocol that provides a congestion-controlled flow of unreliable datagrams. DCCP is intended for time-sensitive applications that have relaxed packet loss requirements. The protocol aims to add to a UDP-like foundation the minimum mechanisms necessary to support congestion control, such as possibly reliable transmission of acknowledgment information.

Several TCP protocol extensions have emerged to overcome the standard TCP limitations, providing more efficient bandwidth utilization and sophisticated mechanisms for congestion control, which preserve the fundamental QoS guarantees for time-sensitive traffic. Sisalem and Schulzrinne (1998) proposed protocols of the family of *TCP-friendly* such as *TCP-friendly rate control* (TFRC) (Goff et al. 2000), where transmission rate is adjusted in response to the level of congestion, as indicated by the loss rate. Multiple packet losses in the same RTT are considered as a single loss event by TFRC, hence the protocol follows a more gentle congestion control strategy. The protocol eventually achieves the smoothing of the transmission gaps and therefore is suitable for applications requiring a smooth sending rate, such as streaming media. However, this smoothness has a negative effect as the protocol becomes less responsive to bandwidth availability (Tsoussidis and Zhang 2005).

REAL-TIME TRANSPORT PROTOCOL

Real-time transport protocol (RTP) (Schulzrinne et al. 1996) is the standard for transmitting delay-sensitive traffic across packet-based networks. The protocol runs on top of UDP or TCP and provides end-to-end network

*Note that although β was so far called the *multiplicative factor*, its value determines the size of the window; that is, $7/8$ means that the window was reduced by $1/8$ th.

**In fact, TFRC has several other mechanisms that differ from TCP.

transport functions, which are suitable for real-time applications over multicast or unicast networks. RTP, in a complementary role, uses the sequence information to determine whether the packets are arriving in order, and it uses the time-stamping information to determine packet interarrival times. The data transport is augmented by *real-time control transport protocol* (RTCP), which allows the monitoring of data delivery. RTP and RTCP are designed to be independent of the underlying transport and network layers.

Papadimitriou and Tsaoussidis ("Evaluating" 2006) study transport protocol performance from the perspective of real-time applications. More precisely, they evaluate TCP and UDP supportive role in terms of real-time QoS, network stability, and fairness. A new metric for the evaluation of real-time application performance is proposed to capture both bandwidth and delay requirements. Using this metric as a primary criterion in their analysis, the authors reach conclusions on the specific effects of wireless links, real-time traffic friendliness, and UDP and TCP protocol efficiency. Furthermore, Papadimitriou and Tsaoussidis ("Evaluating" 2006) quantify the effects of satellite links on TCP efficiency and streaming video delivery.

STREAM CONTROL TRANSMISSION PROTOCOL

Like TCP, *stream control transmission protocol* (SCTP) (RFC 2960) provides a reliable transport service, ensuring that data are transported across the network without error and in sequence. Like TCP, SCTP is a session-oriented mechanism, meaning that a relationship is created between the end points of an SCTP association before data transmission, and this relationship is maintained until all data transmission has been successfully completed.

However, traffic characteristics and requirements of signaling as well as conventional telephony (i.e., SIP traffic) have found TCP too limiting. Easy but still inefficient solutions have incorporated reliable, congestion-aware data transfer in the application layer protocol, which runs on top of the simple, message-oriented UDP. TCP's limitations for such applications can be summarized as follows (RFC 2960 and RFC 3286).

1. The combined reliable data transfer and strict order-of-transmission delivery of data: Some applications need reliable transfer without sequencing of packets, while others would be satisfied with partial ordering of the data. In both of these cases, TCP inevitably causes additional delays.
2. The stream-oriented nature of TCP, which is occasionally insufficient for some applications: Such applications must add their own record marking to delineate messages along with the use of the push field of the TCP header.
3. The limited scope of TCP sockets complicates the task of providing highly available data transfer capability using multihomed hosts.
4. TCP is relatively vulnerable to denial-of-service attacks.

SCTP satisfies the aforementioned requirements. It is positioned between the SCTP user application and a connectionless packet network such as IP. SCTP has been approved by the Internet Engineering Task Force as a proposed standard. The basic service offered by SCTP is the reliable transfer of user messages (in contrast to TCP's bytes) between peer SCTP users. It performs this service within the context of an association between two SCTP end points. SCTP provides the means for each SCTP end point to provide the other end point (during association start-up) with a list of transport addresses (i.e., multiple IP addresses in combination with an SCTP port) through which that end point can be reached and from which it will originate SCTP packets. The association spans transfers over all of the possible source and destination combinations that may be generated from each end point's lists. The name *stream control transmission protocol* is derived from the multistreaming function provided by SCTP. This feature allows data to be partitioned into multiple streams that they have the property of independently sequenced delivery so that message loss in any one stream will only initially affect delivery within that stream and not in others. In contrast, TCP assumes a single stream of data and ensures that delivery of that stream takes place with byte-sequence preservation. Although this is desirable for delivery of a file or record, it causes additional delay when message loss or sequence error occurs within the network. When this happens, TCP must delay delivery of data until the correct sequencing is restored either by receipt of an out-of-sequence message or by retransmission of a lost message.

The SCTP transport service can be decomposed into a number of functions, including sequenced delivery, association within streams, user data fragmentation acknowledgment-based reliable service, congestion avoidance, packet validation, and path management.

SYNERGISTIC APPROACHES

The traditional *drop tail* technique for managing router queue lengths is to set a maximum length for each queue, append incoming packets to the tail of the queue until the maximum length is reached, and then reject (drop) subsequent incoming packets until the queue size decreases because a packet from the head of the queue has been transmitted. On the other hand, *random early detection* (RED (Floyd and Jacobson 1993) drops or marks incoming packets with a dynamically computed probability when the average queue size exceeds a minimum threshold. This probability increases with the average queue length and the number of packets accepted since the last time the packet was dropped. The average queue length, \bar{q} , is estimated as an exponentially weighted moving average as follows:

$$\bar{q} \leftarrow (1 - w) * \bar{q} + w * q \quad (15)$$

where w , the weight of the moving average, is a fixed (small) parameter and q is the instantaneous queue length. As \bar{q} varies from *min th* to *max th*, the packet-dropping probability varies linearly from 0 to *max p*.

An initial drop probability, p , is calculated using a drop function, F , given as:

$$F = \begin{cases} 0 & \bar{q} < \min_th \\ \frac{\max_p(\bar{q} - \min_th)}{(\max_th - \min_th)} & \min_th < \bar{q} < \max_th \\ \max_p + \frac{(\bar{q} - \max_th)}{(1 - \max_p) / \max_th} & \max_th < \bar{q} < 2 \max_th \\ 1 & \bar{q} > 2 \max_th \end{cases} \quad (16)$$

Therefore, F grows linearly from 0 to $\max p$ when \bar{q} increases from $\min th$ to $\max th$, and F grows linearly from $\max p$ to 1 if \bar{q} increases further from $\max th$ to $2 \max th$. The actual probability, P , is a function of the initial probability, p , and a *count* of the number of packets enqueued since the last packet was dropped—that is, $P = p / (1 - \text{count} * p)$. In the original RED buffer management scheme, $F = 1$ if $\bar{q} > \max th$. Later, Floyd recommended the use of the “gentle” variant of RED, which uses the dropping function F above.

RED attempts to provide negative feedback to sending hosts by dropping packets from among various flows probabilistically before the gateway's queue overflows. RED's strategic goal is to prevent high delays and burst drops; it achieves this by dropping packets when contention boosts up (i.e., the queue steadily builds up) before queue overflow. Although packet control is necessarily local, the management perspective of RED is not confined by strict locality: Each drop is expected to trigger a congestion-oriented response from the corresponding sender, and the dropping mechanism selects packets at random, causing more drops to flows that transmit at higher rates. RED's design was intended for TCP and adaptive transport protocols that respond to packet-drop events at the routers. RED, for example, collaborates perfectly with Reno because a packet drop triggers multiple dacks and the sender enters a congestion avoidance phase—unlike Tahoe, which falls back to the initial window size. A great advantage of RED is its implicit synergy: No modification is required to protocol headers of both layers.

CONCLUSION

Transport layer protocols incorporate mechanisms for the delivery of data. There is no standardized functionality for such protocols; they can provide a reliable service, ordering of packets, flow control, congestion control, or application-oriented rate control. Their performance cannot be characterized by a single metric, and there are many trade-offs involved. For example, reliability comes at the expense of time, congestion control has its cost on real-time application performance, and efficiency has its cost on fairness.

More sophisticated protocols have been developed recently to handle specific aspects of applications and allow collaboration—implicit or explicit—with other layers. Because the network lacks a centralized mechanism for monitoring the behavior of users or user applications, the functionality of the transport layer has a crucial role on network stability and resource-sharing capability.

GLOSSARY

Additive increase multiplicative decrease (AIMD):

The standard transport protocol strategy to bring a system into equilibrium.

Congestion: A situation in which buffers are fully occupied and packets are being dropped.

Congestion control: Usually implemented in collaboration by the transport and the network layer. The transport layer regulates the transmission rate, and the network layer drops packets when the network is congested.

Flow control: A widely used mechanism to avoid overflowing in the receiver's buffer.

Goodput: A performance measure of transmitted data over time, excluding protocol overhead and retransmitted data, associated with the efficiency of protocol strategies.

Random early detection or drop (RED): A mechanism to drop packets before congestion occurs in order to avoid multiple packet drops and implicitly inform senders about forthcoming congestion.

Reliable service: A service that guarantees delivery of packets and is usually implemented using buffers at both the sender and the receiver; sequence numbers, time-outs, and acknowledgments.

Responsiveness: A measure of the ability of a system to converge to equilibrium.

Smoothness: A measure of the oscillations during transmission.

INTRODUCTION

The first four layers of the *open system interconnection* (OSI) *reference model* and the *TCP/IP reference model* are roughly synonymous in function: They move network data from one host to the other. Above the transport layer, however, the models differ. The TCP/IP model has one more layer, the *application layer*; whereas the OSI model uses three more—the application, presentation, and session layers—to represent the same functionality.

The OSI model's bottom four layers (physical, data-link, network, and transport) are the most studied by networking neophytes. In stark contrast, the top three layers (application, presentation, and session), which are not completely realized in the TCP/IP model, are often overlooked. The OSI model, designed by committee, explicitly had a goal of specifying layers that would solve the problem of communicating heterogeneous data and creating complex dialogs between varied autonomous systems (see Figure 1). The Internet model, on the other hand, evolved from a developing network focused on moving bits around, not on standardizing software application functions.

Even if the higher OSI layers are not widely implemented in explicit, separate layers, each serves a definite purpose. The presentation layer forces a designer into abstracting the way data are represented, leading to

more maintainable code, better code re-use, and a higher chance of interoperability among communicating processes. Designing for the session layer leads to better management of complicated data streams. Also, fully utilizing the application layer allows for clear modularization of networking services and higher levels of code re-use.

ISO AND ITU REFERENCE LAYER DESCRIPTION

Framework

Work on what would become the OSI reference model began in the late 1970s and culminated in 1984 as the International Organization for Standardization (ISO) international standards document 7498. This standard was actually a joint development with the International Telegraph and Telephone Consultative Committee (CCITT), which has since been reorganized into the Telecommunication Standardization Sector of the International Telecommunication Union (ITU-T).

ISO 7498 is a collection of four documents: 7498-1 (ISO 1994b), *The Basic Model*; 7498-2, *Security Architecture*; 7498-3, *Naming and Addressing*; and 7498-4, *Management Framework*. Over time, supporting ISO and ITU-T standards augmented the basic model, adding in-depth description of the layers' services. Later revisions to the reference documents streamlined or adapted the model to new ideas in the networking world. However, the changes have not shifted the model from its tightly coupled seven-layer framework.

Being a joint effort, each ISO standards document has a mirror recommendation document from the ITU-T. To reduce confusion, the references in the rest of this chapter will refer to the ISO standard document numbers. Table 1 gives a listing of referenced ISO standards, their ITU-T counterparts, and their mappings to the OSI layers. The table is compiled from the 35.100 (open systems interconnection) standards section of the ISO Web site (www.iso.org) and the ITU-T X (data networks and open

system communications) section of the ITU Web site (www.itu.org).

Application Layer

Zimmermann (1980) succinctly describes the six other layers in the OSI model as existing “only to support this layer.” No common network protocols exist here, only end-user processes (or applications) that initiate and receive communications from other application-layer processes. Any software has an application component, but e-mail readers, Web browsers, instant messengers, and multiplayer games are common programs that make good application examples because each relies heavily on the network stack.

The ultimate goal of the application layer is to communicate information, but the OSI model (ISO 1994b) identifies other possible responsibilities for the layer:

- communicating processes’ addresses,
- quality of service acceptable for the communications link,
- process error recovery obligation,
- security requirements,
- process synchronization, and
- requiring abstract syntaxes.

Larmouth (1995) gives a good overview of the history of the application layer and the motivations behind changes since its inception. When the OSI model first defined the application layer, it did so with the idea that applications are large, monolithic pieces of software with a tightly structured access to presentation-layer services. It broke the application entity (the portion of the application that provides OSI model support) into two parts: the user element and the *application service element* (ASE). The user element depended on the ASE for communication functionality as well as for providing an interface to services in the lower layers. The ASE itself was broken in two main modules: the *specific-application service element* (SASE) and the *common-application service element* (CASE). SASEs were network pieces custom to the specific application such as database access or file sharing.

Common-application service elements were networking elements used by many different applications. Different CASEs can be used many times in a single application entity. The OSI model originally defined four CASEs:

- *association control service elements* (ACSE) create an associative link between applications in preparation for network communications (ISO 1996a);
- *remote operations service elements* (ROSE) create a request-reply mechanism to allow for remote operations across the ACSE link (ISO 1989b);

- *reliable transfer service elements* (RTSE) allow reliable messaging while keeping the more complicated lower layers transparent (ISO 1989a); and
- *commitment, recurrence, and recovery service elements* (CRSE) act as coordinators for multiple application communications (ISO 1998).

In the 1980s, the structure of the application layer was changing. The concept of the user element was removed, and the CASE and SASE elements were combined into an application service element. Applications were now thought of as a collection of ASEs. Each ASE used a set of *service primitives* to communicate with the presentation layer and provide a high-level service (from which more ASEs could be built). This *nested service primitives model* provided a problem to an application programmer because of the complexities that could arise from naively combining ASEs. It would be ambiguous from looking at just the ASE primitives as to which lower-level services were mapped to the ASE; this would lead to multiple synchronization points (when the developer wanted only one) or incorrect ordering of messages through the combined ASEs.

Later in that decade, a new application-layer standard (ISO 1994a) created a new *application-layer structure* (ALS). Developed from a concern about coordinating network activity over more than one connection, the ALS defined new building blocks for an application entity. First, it grouped all ASEs for a single application association into a *single association object* (SAO). Within each SAO was a *single association control function* (SACF) that managed the ASEs. An application entity might have multiple SAOs and these were grouped into a *multiple association object* (MAO). Likewise, the MAOs were controlled by a *multiple association control function* (MACF).

Unfortunately, the new ALS did not address problems in the *commitment, concurrency, and recovery* (CCR) and *transaction processing* (TP) standards (ISO 1992, 1998). Briefly, these standards are concerned with the use of consistent operations. An example of keeping consistent would be a banker moving money between two institutions. The complete transaction requires two separate subtransactions (a debit and a credit), but the transaction would only be valid (i.e., consistent) if both subtransactions were successful. In other words, each action should only be committed if successful and, likewise, the other action also successful. One solution is to implement a two-phase commitment system. A related concept in TP is *atomic* transactions that are all-or-nothing operations that guarantee database consistency.

Amendment I of ISO 9545 (1994) addressed the CCR and TP problem by almost completely rewriting the standard to create the *extended application-layer structure* (XALS). The first major change was moving the SAO, MAO, SACF, and MACF concepts from the main text and into an annex because it was decided they were not necessary for combining ASEs. The concept of an *application service object* (ASO) was added, reflecting the shift to objects at the start of the 1990s. Each ASO was a collection of one and only one *control function* (CF) and a collection of ASOs or ASEs. Each ASE was defined to be basic and with no component parts. With this new structure,

an *application entity* was defined as the outermost ASO. In addition, this outermost ASO's CF was the service that specified the presentation services instead of having the ASEs specify them.

Another choice an application must make is the mode of connection. The OSI model defines two types of network communications initiated by an application: *connection-oriented* (connection mode) and *connectionless-oriented* (connectionless mode). Connection-oriented communication requires that cooperating processes follow a standard protocol to establish, maintain, and tear down the communications link. Connectionless-oriented information transfers have no explicit link setup (to be useful, of course, the receiving processes must at least listen for any incoming data).

The choice between a connection- or connectionless-oriented data transfer by the application layer is determined by factors such as overhead allowance, transmit speed, and message complexity. The choice can also affect how lower layers construct and transmit their data. In fact, the OSI model allows certain layers (physical, data-link, network, and transport) to convert between modes. However, the session and presentation layers are never allowed to convert between different modes: They are tied to the application's layer mode.

Presentation Layer

The penultimate layer of the OSI model is the presentation layer (ISO 1994c). Because it is not guaranteed that communicating processes will share the same representation of data, it is the job of the presentation layer to provide services to allow applications to transform their data into representations that other applications can understand. A classic and simple example of different data representations is the case of ASCII systems communicating with terminals using EBCDIC characters. In more complex cases, an application has a highly structured data representation that needs more than a simple one-line conversion routine.

Each application's data are considered to be encoded by a language, or *syntax*, and the presentation layer utilizes a special *transfer syntax* to solve the problem of moving data between the two representations. There can be more than one usable transfer syntax for a given application's abstract syntax. Combined with the fact that each application can have more than one representation for its data, multiple combinations of transfer syntaxes and abstract syntaxes may be possible. The ISO model defines a *presentation context* as a singular abstract and transfer syntax association. Each combination is a unique set to an application entity, and each is usually assigned a unique identifier. Multiple presentation contexts could be pairs of abstract and transfer syntaxes that are disparate in nature or simply syntax pairs that have different parameterizations. It is up to the application to define each presentation context.

When a connection-mode link between applications is established, the two communicating presentation layers must negotiate the transfer syntaxes to be used. The originating side sends possible syntaxes available to it, so the receiving presentation layer can choose the transfer

syntax it understands. In connectionless-mode, the sending presentation layer chooses a transfer syntax with no negotiation. However, the receiving application must be able to translate the chosen syntax, so usually there would need to be an a priori selection of a transfer syntax.

Service Primitives

The application layer accesses the presentation layer's service primitives through the *presentation-service access point* (PSAP). The presentation layer has only one unique primitive of interest: the *P-Alter-Connect*. This primitive allows the negotiation of the presentation context discussed previously.

The rest of the presentation primitives are mirrors of the session-layer primitives. These copies give an application entity, which only has direct access to the presentation layer, access to the myriad session services. Replicating functions is the price for keeping a tightly layered model, but there is one difference between the session and presentation primitives: Whereas the session primitives have strings of octets as their data values, the presentation primitives have the same data in the applications abstract syntax. This transformation is the result of the application of the transfer syntax and its encoding rules.

Abstract Syntax Notation 1 and Basic Encoding Rules

The representation of a transfer syntax itself requires a standard notation to allow for wide-scale re-use of data definitions and operability between heterogeneous systems. *Abstract syntax notation 1* (ASN.1) is a joint ISO and ITU standard notation to do just that (ISO 2002a). ASN.1 is a textual language that is powerful enough to represent data structures that have recursive or nonmandatory elements. Before ASN.1, previous attempts at a standard notation included the *Backus-Naur form* (BNF) notation. Yet no standardization for BNF materialized, even though it was a powerful enough language (Larmouth 1995).

The ASN.1 is based on a set of primitive (e.g., Boolean, integer, real) and structured (e.g., set, sequence, choice) types to define a data representation. These types can be assigned values and organized into modules. Additional language features incorporate the ability to include subtyping and recursion. ASN.1 included a macro notation before 1994 when the introduction of the *information class object* deprecated it. Information class objects are similar to macros except they are placed within an object framework.

Before an ASN.1-defined transfer syntax can communicate data, the ASN.1 structures must actually be converted, or encoded, into a bit stream of octets. Because of the desired flexibility of ASN.1 and the presentation layer itself, these encoding rules are separate from the ASN.1 language. Encoding rules for ASN.1 include *basic encoding rules* (BER), *canonical encoding rules* (CER), *packed encoding rules* (PER), *lightweight encoding rules* (LWER) and *XML encoding rules* (XER).

Briefly, the use of a *type, length, and value* (TLV) encoding scheme can describe BER (ISO 2002b). ASN.1 encodes primitive types as a TLV triplet. ASN.1 structured types are recursively defined by having a nested TLV within an encapsulating *value* field (which is in its own TLV triplet). Each TLV field translates to a whole number of octets; in

most usages, the type (T) and length (L) fields will impose a two-octet overhead for every primitive. Other encoding rules such as PER attempted to decrease this high overhead of BER. Usually, though, reduced overhead means encoding complexity and CPU usage increase. Although other rules attempted to do the opposite, LWER is meant to have a fast processing time, but not necessarily the most compact form. Other encoding rules, such as XER, encode ASN.1 into standard and popular document languages such as *extensible markup language* (XML).

Session Layer

The session layer manages the “dialogue” between two communicating application entities. For a connectionless-oriented link, the only function the session layer performs (besides error handling) is to provide any transport-to-session address mappings. In a connection-oriented link, services include:

- establishment and release of the session,
- selection of normal or expedited data transfer,
- management of tokens,
- management of activities,
- checkpoint synchronization and resynchronization, and
- handling of exceptions.

The rest of the session-layer description focuses on the activities in a connection-oriented session (ISO 1996b).

During the establishment of the session, the higher presentation-layer entities establish a session connection and can cooperatively set any parameter values needed for the dialogue. The session layer also provides an orderly session release for the presentation entities without losing data. In addition, with a risk of data loss, the higher presentation or session layer can abort a session.

Again, Larmouth (1995) gives a description of the motivations behind the creation of the session layers and the problems they attempt to solve. Many of the session layer's services developed in a time of unreliable and slow links. The establishment of checkpoints and their resynchronization between two applications were driven by communication failures that forced a retry of a data send. If these data constituted a large file, then it would be helpful if the network stack could periodically create synchronization points where two applications could reset and start their communications over again without restarting from the beginning.

The session layer provides two types of synchronization: minor and major. *Minor* synchronization is usually used when only one application (simplex) is talking because of the reduced complexities. During a minor checkpoint, the sending application inserts a marker (actually a type of session token) into the data stream. Once the receiving application reads this marker, it knows that the two applications have a common point at which to restart their monologue. *Major* synchronization is used when two applications are both communicating (duplex). The algorithm for the major synchronization is outside the scope of this chapter, but it allows for resynchronizing applications to have common checkpoints in the data stream.

The use of tokens in the session dialog was primarily created to overcome a specific issue in duplex links. Historically, many network protocols (and their applications) become simpler if the communicating applications do not talk simultaneously. One advantage of this is that software does not have to worry about an input and an output queue at the same time. One option is for the applications to take turns sending data, which the session layer implements with a special token. The token is appended to the data stream whenever a sending application is finished with its current communication and acts as a signal for the other application to begin sending.

With modern computers able to multitask and most languages able to support threading, multiple sending and receiving queues are trivial to implement, thus eliminating the requirement for tokens. Fast and reliable links have reduced, but not eliminated, the need for check-pointing.

The concept of a session activity comes from the days of Teletex communications. The document transmissions were independent activities and marked as such. Today, of course, the use of this activity has little benefit for the majority of non-Teletex applications. However, the application entity has full control of the session activity services and can use the activity primitives to divide its dialogue into arbitrary activities.

Service Primitives

Without going into detail about each one, the numerous session primitives fall into fourteen functional units: kernel, negotiated release, half-duplex, duplex, expedited data, typed data, capability data exchange, minor synchronize, symmetric synchronize, major synchronize, resynchronize, data separation, exceptions, and activity management. As said earlier, these primitives repeat at the presentation level.

TCP/IP PROTOCOL SUITE EXAMPLES

The only layer the TCP/IP explicitly defines of the OSI's top three is the application layer in RFC 1123 (Braden, 1989). RFC 1123 is a far different document than the OSI application standard. The RFC does not define service elements or submodules in the layer. Instead, it gives a brief introduction of the goals of application development (such as error logging and robustness) and then describes certain requirements that applications must follow (such as host names and numbers and type of service). However, the bulk of the document is a description of the basic types of applications found on the Internet: telnet, file transfer protocol (FTP), simple mail transfer protocol (SMTP), and domain name service (DNS). This may not seem the best way to set a standard, but it follows the basic philosophy of the Internet: Creation is through usage, not through a priori standards.

It is generally considered that the TCP/IP's application layer subsumes the OSI presentation and session layers, but there is no explicit mention of this subsumption in the TCP/IP *Request for Comments* (RFC) (Socolofsky and Kale 1991, for example). With no explicit layers or protocols to handle presentation or session functions, application designers are free to develop their own representations and

protocols. Over time, many of these developments have become de facto standards and textbook examples to map back to the OSI model. The problem with direct mapping of TCP/IP protocols to OSI layers is that TCP/IP software will encapsulate functionality from many layers into a single protocol that cannot be mapped to a specific OSI layer. The following examples will show off the overlapping layer services.

TCP Session Establishment

The TCP connections created between two applications are commonly called *sessions*. These sessions, which are simply the TCP/IP transport protocol handling connection establishment and control (Iren, Amer, and Conrad 1999), really do not map to the OSI session layer. The session layer provides services to the data streams that flow across the TCP-created link.

World Wide Web

Because of its ubiquity and popularity, the World Wide Web has become almost synonymous with the Internet. The advantage of separating the Web browser from the underlying data representation and services becomes apparent when one considers the numerous combinations of browsers, multimedia, and page languages that exist.

Web pages are served to a browser through the *hypertext transfer protocol* (HTTP) (Fielding et al. 1999), which is a fairly simple protocol and is usually considered at the application level, although its services can be mapped to the session layer. Its ability to create persistent Web connections gives HTTP session-level services. Before HTTP 1.0, a Web browser required separate TCP connections to download each element of a complex Web page. However, newer versions of HTTP keep a TCP connection open and stream in the different Web elements with a series of "get" statements. This "pipelining" raises the efficiency of downloading intricate Web pages, thus decreasing load time.

Even though the different elements of the Web page are primarily encoded in *hypertext markup language* (HTML), a varied number of other formats also can be found on a served page, including pictures, animations, music, and movies. These formats are specified as *multipurpose Internet mail extensions* (MIME) content types in the HTTP messages. This presentation-layer service allows the Web browser to identify content type and determine the compatibility to play it, as well as allow the user to install software for unknown MIME content (Freed and Borenstein 1996).

Hypertext transfer protocol secure (HTTPS) is the secure form of HTTP. It is not a separate protocol per se, but simply HTTP implementing a type of encrypting protocol such as *transport layer security* (TLS) or its predecessor *secure sockets layer* (SSL). Being a type of encryption, TLS (Dierks and Allen 1999) would seem to naturally fall into the presentation layer, even though it does have the word *transport* in its name. Indeed, the actual encryption of the Web page can be seen as existing at the presentation level because the encryption represents just another type of data representation. Also, the exchange of certificates and other encryption parameters could be a type of data

representation negotiation. Yet TLS can also be mapped to the session layer, because it forms its own session (connection) between host and client and manages this data stream. It is protocols such as HTTPS—a combination of two protocols that both share services between the presentation and session layers—that make it a nontrivial problem to map real services based on the TCP/IP model directly to the OSI reference model.

Distributed Applications

Whereas serving a Web page is a simple request-and-receive transaction, data communications between many distributed applications become more complicated once processes need to distribute objects or execute remote code. The following common distributed services are mapped to the OSI model as we explain.

Named Pipes

A *named pipe* is a method of interprocess communication in UNIX and other operating systems (although other operating systems may have different operational semantics). A named pipe is a persistent service that allows processes to connect and disconnect with it (unlike an *unnamed pipe*, which is destroyed when the process that created it has finished). A named pipe can manage multiple flows within it by allowing multiple applications to connect to it through access points in the file system. Named pipes also implement session commands such as `O_NONBLOCK`, which allows for non-blocking read or write commands. The named pipe is one of the classic examples of mapping a real, common service to the session layer.

Remote Procedure Call

A *remote procedure call* (RPC) is a method for executing code remotely. An RPC (Sun Microsystems 1988) is generic in itself, but there are several RPC versions: *open network computing* (ONC), *distributed computing environment* (DCE), and ISO RPC to name a few. Barkley (1993) compares these different versions nicely. Each RPC has an associated representation. ONC RPC has *external data representation* (XDR), DCE RPC has *network data representation* (NDR), and ISO RPC has ASN.1 (of course!). Riding on top of the transport layer, RPC allows a process to transparently call a procedure even if the target machine is local or halfway around the world.

Barkley (1993) admits that there is some argument, however, as to where a remote procedure call fits on the OSI model. Because it requires a presentation-level data representation for communicating between heterogeneous environments, one argument is that an RPC is strictly an application-level service. This does fit the layering of the OSI model.

The counterargument is that RPC provides enough “dialogue” manipulations to make it a session-level service and the presentation-layer representation should be simply relegated to a common data encoding (instead of an entire presentation-layer protocol). Session services include:

- transaction IDs to match request and replies,
- versioning for both the RPC protocol and participating applications,

- authentication fields, and
- error handling.

Voice over Internet Protocol

Internet telephony, otherwise known as *voice over Internet protocol* (VoIP), is becoming a common alternative to traditional POTS (plain old telephone system) phones or even cellular phones. Entire books have been written about this new Internet service, but this section will briefly describe some of the high-level protocols and services of VoIP and how they map to the top three OSI layers.

End-user applications for VoIP include POTS telephones plugged into analog-to-digital routers to telephony software running on a personal computer. Regardless of the interface, the application has the function of presenting and receiving the multimedia of the communications and allowing user-level control of the call. The application also determines the actual services that need to be implemented at the lower levels. For example, a simple analog phone will not need any video *coders-decoders* (codecs). Likewise, a static PC-to-PC connection would have no need for three-way calling services. However, by keeping the application functionality modularly separate from the lower levels, application hardware or software is upgradeable and user privileges changeable, thus minimizing upgrade costs.

H.323

Below the VoIP application layer, H.323 (International Telecommunication Union 2003) is an umbrella standard that includes large set of protocols and services for VoIP call setup, management, and teardown. Several protocols in H.323 are usable as example mappings to OSI's presentation and session layers.

The H.323 presentation-layer services generally comprise codecs that are used to encode and decode the voice communications. Each codec runs a different encoding rate, leading to different levels of voice quality. Some common codecs include G.711 (64 kbps audio), G.729 (8 kbps speech), and G.723.1 (5.3 or 6.3 kbps speech). Video codecs are available as well, including H.261 and H.263. Keeping the codecs at the presentation layer allows VoIP systems to change data-encoding rates to match network congestion or update newly released codecs without modifying the user application.

A bulk of the call management responsibility falls on the transport layer, but some session-level services also affect the media stream or call dialogue. Services at the transport layer and below are grouped in a *call signaling* class. Functionality that controls the communication stream are called *call control* services and include the management of the different media (audio, video, and text) that can be sent across a VoIP connection and the exchange of capabilities so each end-point application knows which media streams and data rates can be used.

The *registration admission status* (RAS) messages facilitate gateway discovery and registration, name resolution (IP address ↔ H.223 address), admission and bandwidth control, and status requests. Along with RAS, protocol H.245 provides services that could map to the session layer. The H.245 protocol allows the setting of a

master-and-slave configuration, exchange of capabilities, and management of the multimedia streams. Both of these protocol's messages are encoded in the independent representation ASN.1.

Sun Microsystem's Network File System

Introduced in 1985, Sun Microsystem's *network file system* (Sun-NFS) has functionality that can be mapped to all three upper layers. Sun-NFS was designed to be independent of the operating system, machine, and even transport architecture. This transparency has made it a popular file system, especially in the UNIX world. Sun-NFS is currently at version 4 (Shepler et al. 2000), with this recent version simplifying and unifying the protocol.

The application services of NFS are the procedures and operations that a user or another process can perform. Standard file operations include opening, writing, closing, locking, and attribute modification. End users may directly use the Sun-NFS through the operating system or through a secondary process interacting with the file system.

At the presentation level, NFS uses *external data representation* (XDR) as its data-representation language. Less general than ASN.1, XDR focuses more on actual systems. For example, XDR assumes *real* numbers conform to the IEEE floating point standard representation. ASN.1 also is more expressive, because XDR has no module capability or macro functionality. However, XDR can be significantly faster in encoding and decoding, and it is certainly a simpler representation language than ASN.1.

SUN-NFS has a session service built over the transport layer that is independent of any transport connection. This session allows voluntary or involuntary disconnections without server context loss. These sessions also cache authentication-service settings.

Sun-NFS uses Sun's *open network computing* (ONC) RPC to call its remote file methods on the network. Because of Sun-NFS the ONC RPC has become one of the more prevalent remote procedure call flavors. In addition to the normal RPC commands, Sun-NFS version 4 added a *compound* service functionality to its RPC operations that provides greater session functionality. The COMPOUND command allows multiple file operations using one RPC request, therefore increasing the efficiency of file system operations.

CONCLUSION

The OSI reference model provides for a highly detailed model for distinct application, presentation, and session layers. Clearly, not every application needs or uses the explicit layering described by the model. If they do, then most common applications do not tightly structure their code as much as the OSI model has detailed, especially in the application layer.

However, not taking any design requirements from the OSI model because of its complexity is like throwing the baby out with the bathwater. Separating out session and presentation services is a way of reducing the complexity of programming applications on the Internet. With many distributed applications handling multiple remote clients

on different platforms, separating out dialogue (session) and representation (presentation) functions from the main functionality of the software can only be described as good design. With changing network topologies and newer hardware, programmers can focus software changes at particular layers without affecting the end-user functionality. It is the author's opinion that any future construction of a new networking framework will include some features of the OSI's application, presentation, and session layers, albeit in a form that is more friendly to real-world network programming.

GLOSSARY

Application layer: The seventh (top) layer in the OSI model and TCP/IP reference models. In the OSI model, the layer below it is the presentation layer. In the TCP/IP reference model, it is the transport layer.

Extensible markup language (XML): A markup language designed to specify many different types of data using tags. Its standards body is the World Wide Web Consortium (W3C).

Hypertext transfer protocol (HTTP): The protocol used in communicating pages on the World Wide Web. The current version is 1.1.

International Organization for Standardization (ISO): An international body that creates standards ranging from manufacturing processes to data communications.

International Telecommunication Union (ITU): An international body that creates standards (or recommendations) specializing in telecommunications (radio, satellite, and networking, among others).

Open system interconnection (OSI) reference model: An abstract network model defined in numerous ISO standards. The layers are application, presentation, session, transport, network, data link, and physical. The model defines services at each layer and describes how each layer interacts with the layers above and below it to transmit data.

Presentation layer: The fifth layer in the OSI model. The layer provides services to translate data between different syntaxes. The TCP/IP model does not implement this layer.

Remote procedure call (RPC): A protocol for executing programs remotely.

Session layer: The sixth layer in the OSI model. The layer provides services to manage the flows, or dialogues, of applications. The TCP/IP model does not implement this layer.

Syntax: The rules that define a correct language. In data communications, sending and receiving computers may use different syntaxes to encode their data. Before use, a process must translate foreign syntaxes into usable ones.

TCP/IP reference model: A set of protocols and standards that the Internet and most commercial networks implement. The model is chiefly defined in documents known as Requests for Comments (RFCs).

Voice over Internet protocol (VoIP): A protocol used to transmit and receive voice communications over a network.

INTRODUCTION

Digital information transmission systems can be used to transmit signals that are originally in *digital* form (i.e., at a given time the signals can only take a finite set of allowed values within their input range) or transmit signals that are originally *analog* in nature (i.e., at any given time they can take any values within a given input range). Note that the range in question could be amplitude, phase, or frequency. Analog signals, however, must undergo a procedure called *analog to digital conversion* before they can be digitally transmitted (we discuss this later).

The section starts with comments regarding the idea behind digital information transmission and an empirical description regarding the effect of noise in these systems followed by a comparison between digital information transmission and analog information transmission. Digital data transmission technology is then summarized, starting with analog to digital conversion, channel bandwidth, *baseband transmission* (transmission of information at the same frequency range in which the information originated), *passband transmission* (i.e., transmission of information at a frequency that is upshifted, with respect to the original range, to a much higher frequency range). Next, the different modes of transmission and signaling schemes are reviewed, followed by a formal discussion regarding digital transmission systems affected by noise.

INFORMATION TRANSMISSION: ANALOG VERSUS DIGITAL

Analog versus Digital Signal Transmission: A Comparison

When an analog information waveform, such as that produced by a musical instrument, is transmitted using an analog system, it is desirable that the same waveform (except for a delay and some attenuation) appears at the receiver input. Any change, because of ever-present channel noise, in the decoded signal constitutes a distortion and

cannot be undone. Therefore, the main objective of the analog systems is to reproduce the analog waveform with as much fidelity as possible. As such, the ratio of the signal power to the noise power—that is, *signal-to-noise ratio* (SNR)—appears to be the best measure for rating system performance in meeting the stated objective. The larger the SNR, the better the analog system performance.

For the remainder of the discussion, keep in mind that an analog information waveform can be digitalized by a procedure called *analog-to-digital conversion*, after which the signal can also be handled by a digital transmission system (the idea is discussed in depth later). The idea behind digital transmission is based on transmitting only a finite set of distinctive waveforms (symbols). A number of these symbols can be used to encode each finite allowed signal level within the signal input range. In this case, because each transmitted symbol is known a priori, the receiver task is simply to determine from the received noisy signal which symbol actually arrived. The more dissimilar the symbols (symbol *distance*), the less chance of making the wrong identification. Clearly, the best measure for rating the performance of such a system in the presence of noise is the error rate at the receiver decision stage. This is called *symbol error rate* (SER); as we will see, it is closely related to the *bit error rate* (BER) or *probability bit error* (P_b). The smaller the bit error rate, the better the digital system performance.

Noise in Communication Systems: Digital versus Analog

One advantage of digital transmission is that each time the receiver makes a correct decision, the effect of channel noise on the current symbol is completely removed. This is also useful when information needs to be transmitted over long distances. In such cases, the effect of channel noise can be diminished by breaking the long channel path into several segments, each using regenerative repeaters that detect and *regenerate* the arriving symbol to its

original form (thus improving the SNR by eliminating input noise); they can then be retransmitted along the next channel segment. As a consequence, the effect of noise within each individual channel segment is not compounded when the overall channel is considered. Repeaters that boost the signal power can also work as an advantage for analog transmission systems; unfortunately, they also increase the received noise power. Note that these are not *regenerative* repeaters. In practice, the SNR is actually degraded at the output of each repeater of analog information because of the addition of internal repeater noise. For analog systems, to maintain the same SNR as the number of repeaters increases, the transmitted power must be increased linearly (Proakis and Salehi 2005).

As another example of analog versus digital transmission, consider *frequency modulation* (FM) and *pulse code modulation* (PCM), both of which are studied later. These are well known to exchange bandwidth for SNR. Consider that doubling the transmission bandwidth in FM quadruples the SNR, whereas only a small increase of 12.5 percent in bandwidth for PCM systems is required to achieve the same improvement in SNR. On top of this advantage, PCM systems can also use regenerative repeaters along the transmission path as described above (Lathi 1998).

Summary of Advantages: Digital over Analog Information Transmission

Some of the advantages of digital information transmission systems over analog information transmission systems involve their behavior in the presence of noise. One advantage, for example, is the use of regenerative repeaters in digital communication; this allows the signal to be restored at the end of each channel segment, thus preventing the accumulation of errors. This permits the transmission of signals without (or with little) distortion over long distances. Analog systems, on the other hand, can transmit analog messages over maximum distances that are limited by the available transmitting power. Digital systems also have the capacity to do highly sophisticated preprocessing and post-processing of data, digital storage of data and error correction, and error detection. Note that digital transmission lends itself to the use of techniques such as time division multiplexing and code division multiple access systems, particularly in the form of *direct sequence spread spectrum*. The use of microprocessor-based digital hardware allows system upgrades by doing software updates. This is the only way to upgrade, for example, the systems of distant deep space probes. Digital data transmission systems are also amenable to encryption schemes for security and privacy protection. Finally, there is the issue of cost. The cost of digital hardware has been decreasing steadily with time while its performance and capacities have been increasing at an incredibly fast pace.

DIGITAL DATA TRANSMISSION: AN OVERVIEW

Digital Transmission Systems

The following sections describe with detail some of the main aspects of digital information transmission.

The first step in transmitting an analog signal through a digital system will be to sample the signal in order to change it from the continuous time domain to the discrete time domain. The amplitude of each sample will then be encoded using a finite number of bits. This will map the amplitude of each sample to one of a finite set of allowed amplitude values (the *quantization stage*). At this point, the signal changes from analog (sample amplitudes can take any value within a range) to digital (amplitude can have only a finite set of allowed values within a range). Each amplitude level is therefore encoded using n quantization bits that are then transmitted through a baseband channel using the selected line coding. Within this topic, there are several issues such as synchronization, bit error rate, line coding, baseband transmission, passband transmission, and others that will be tackled later.

Analog-to-Digital Conversion: Sampling

The *sampling theorem* is a fundamental tool that supports the conversion of signals from the continuous to the discrete time domain for further processing. Because most real-world signal sources have amplitudes that vary continuously within a range (analog signals), they are usually converted into digital form. The first step in the digitalization process is *time sampling* followed by the second step, *quantization*, which converts the time sample's amplitude into a stream of digital symbols. Each stream encodes one of a finite set of allowed amplitudes values or quantization levels. The second step is where the actual analog-to-digital conversion (A/D) occurs. The time sampling procedure is discussed next, and later some A/D converters are described.

The Sampling Theorem

Let $g(t)$ be a band-limited baseband analog signal with highest frequency component of B Hz, and let $g_s(t)$ be a discrete time signal obtained from $g(t)$ by sampling it at discrete instants in time: $t_n = nT_s, n = 0, \pm 1, \pm 2, \dots$. If the sampling interval is constrained to $T_s \leq 1/(2B)$, then the original continuous time signal, $g(t)$, can be perfectly reconstructed from its samples in $g_s(t)$ (Oppenheim, Schaffer, and Buck 1999). Should $g(t)$ be a non-band-limited signal or band limited to a frequency higher than B , then an *anti-aliasing* filter must be used before sampling at $T_s \leq 1/(2B)$ in order to band limit the signal to B Hz. Note that the sampled signal is a discrete time analog signal because the amplitude of each time sample is still analog—that is, it can vary continuously within the signal amplitude range. The sampling operation can be mathematically modeled as a multiplication of the continuous time signal by a train of impulse functions:

$$g_s(t) = g(t) \sum_{n=-\infty}^{\infty} \delta(t - nT_s) \quad (1)$$

If the analog signal $g(t)$ has a Fourier transform $G(f)$; $g(t) \Leftrightarrow G(f)$ then the sampled signal, $g_s(t)$, has a periodic spectrum, $G_s(f)$, with spectral replicas centered at

frequencies nf_s (Lathi 1998; Oppenheim, Schaffer, and Buck 1999); that is,

$$g_s(t) \Leftrightarrow G_s(f) = \frac{1}{T_s} \sum_{n=-\infty}^{\infty} G(f - nf_s) \quad (2)$$

where $f_s = 1/T_s$ is the sampling frequency and $f_s = 2B$ is called the *Nyquist rate*, or minimum rate at which a band-limited continuous time signal can be sampled without the occurrence of aliasing. In general, when there is aliasing, or overlap of the spectral replicas in the spectrum of the sampled signal $G_s(f)$ (see Figure 1b), the original signal cannot be reconstructed from its samples.

The continuous time signal, $g(t)$, can be reconstructed if we recover its original spectrum from among the spectral replicas corresponding to the spectrum $G_s(f)$ of the sampled signal $g_s(t)$. This can be done by filtering the sampled signal with an ideal *low-pass filter* (LPF) with cutoff frequency B Hz and impulse response $h_{LP} = 2B \text{sinc}(2\pi Bt) =$

$$2B \frac{\sin(2\pi Bt)}{2\pi Bt}. \text{ Hence,}$$

$$g(t) = g_s(t) * h_{LP}(t) = \sum_{n=-\infty}^{\infty} g(nT_s) 2B \text{sinc}[2\pi B(t - nT_s)] \quad (3)$$

where $*$ is the convolution sign and the sinc function is as defined above.

The sampling operation in both time and frequency domain is depicted in Figure 1. Sampling in time corresponds to a periodic replication of the original spectrum in frequency. It is clear by looking at Figure 1b that if sampling is done at less than the Nyquist rate— $f_s < 2B$ —then there will be an aliasing effect whereby the spectral replicas will overlap and perfect reconstruction by using an ideal LPF will not be possible. Note that this particular figure assumes $f_s = 2B$ and therefore the maximum frequency content in the signal is assumed to be $B = f_s/2$. In practice, f_s is usually selected strictly greater than $2B$.

The sampling theorem gives a clue about the *maximum information rate* that can be transmitted without errors through a noiseless channel of bandwidth B Hz. Assuming no noise, such a channel can transmit error free a signal band limited to B Hz. Because a signal of bandwidth B Hz can be completely reconstructed from samples taken at the rate $f_s = 2B$ Hz (note that these samples are independent because they are taken at the minimum sampling rate that allows signal reconstruction from its samples), this implies that a noiseless channel of bandwidth B Hz is able to transmit error free a maximum of $2B$ *independent* pieces of information per second, which is equivalent to, say, two independent pieces of information per second per Hz of bandwidth (Lathi 1998).

In practice, a periodic train of pulses of finite width is used instead of a train of delta functions. In this case, the spectral replicas that appear in the spectrum of the sampled signal are not identical to each other. The baseband spectral replica, however, is an undistorted version of the original signal spectrum. Therefore, the original signal can still be recovered by passing the sampled signal through a low pass reconstruction filter.

Pulse Modulation

The idea behind *pulse modulation* is to sample the analog information waveform and use the amplitude value of each sample to alter one of the parameters of a pulse placed at the sampling point. Depending on the pulse parameter being changed—namely, pulse amplitude, pulse position, or pulse width—this method leads to pulse amplitude modulation (PAM), pulse position modulation (PPM) or pulse width modulation (PWM). These techniques will be discussed in detail elsewhere in this handbook.

In *instantaneous sampled* or *flat-top* PAM, the amplitude of each pulse at time nT_s is equal to the amplitude of the sample value at time $t_n = nT_s$; $g(nT_s)$ (see Figure 2). Note that this PAM signal is still analog because the amplitude of the pulses can vary continuously within a range. Afterward, the PAM signal can be converted into a digital signal by quantizing the amplitude of each pulse, thus

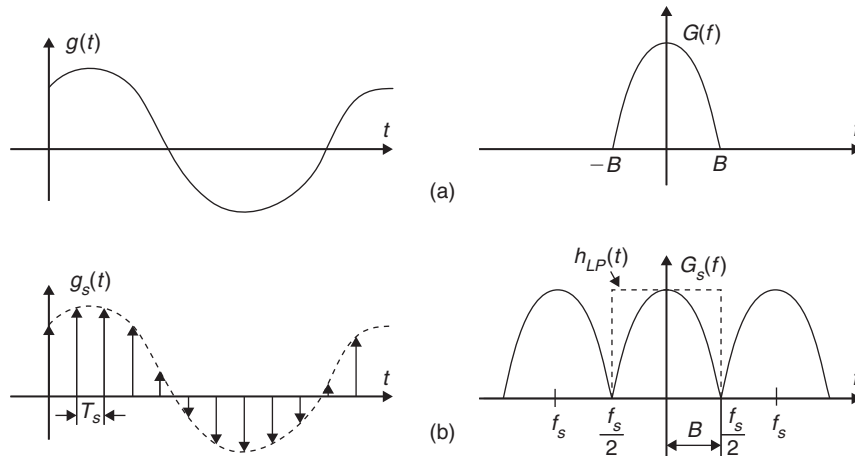

Figure 1: Sampling of analog signals and their reconstruction—(a) analog signal and its Fourier transform, (b) sampled signal and its Fourier transform

Figure 2: Flat-top or instantaneous sampled pulse amplitude modulation

Figure 3: Baseband digital transmission system

permitting only a finite set of values to be the allowable amplitude values. So the conversion of a continuous time analog signal to a PAM signal could be considered a first step in the full digitalization of the signal (Proakis and Salehi 2005; Lathi 1998). A second modality called *natural sampled PAM* discussed elsewhere in this handbook.

Baseband Digital Transmission

A baseband information signal has a low frequency spectrum concentrated around frequency $f=0$ and it is transmitted within the same frequency range. For a baseband digital transmission system, a digital source and a line encoder are needed. An *analog-to-digital converter* (A/D or ADC) is also needed to transform the analog information waveform into a digital data source (Figure 3). Baseband modulation schemes such as *pulse code modulation* (PCM), *differential pulse code modulation* (DPCM), and *delta modulation* (DM) are considered later in this section.

PCM: Quantization and Companding

PCM can be seen as an application of analog-to-digital conversion technology. In the first stage, an analog signal is transformed into a flat-top PAM signal; in the second stage, each amplitude level of the resulting PAM pulses are encoded into finite length digital words (Lathi 1998; Couch 2001; Electrical Engineering Training Series undated). The block diagram of a PCM system is shown in Figure 4. The fact that the analog amplitude of each pulse

is converted into a finite length digital word means that there is only a finite set of “legal” values or levels (quantization levels) that can be adopted to describe the amplitude of each pulse.

An n -bit quantizer assigns the closest of the $2^n = M$ quantization levels as the quantized amplitude of each pulse. The difference between the analog amplitude and the quantized amplitude is called the *quantization error*. If we consider that for each sample value there is a corresponding quantization error value, then we can talk about a quantization error signal. It can be shown that such an error signal can be modeled as a white noise signal whose amplitude values, which can be positive or negative, have a uniform probabilistic distribution within the length of a quantization step (constant probability density function). Thus, the side effects of quantizing the signal are basically the same as those of adding noise to the signal. Those effects are therefore called *quantization noise*. When uniform quantization is used, the quantization step is $\Delta = 2g_p/M$, where g_p is the peak value of the flat-top sampling signal, $g_{FT}(t)$, $2g_p$ is the total amplitude range, and M is the number of quantization levels. Assuming that the quantization error is uniformly distributed in the range $(-\Delta/2, +\Delta/2)$, the variance or power of the quantization noise is $\sigma_\Delta^2 = g_p^2/3M^2$, and the *signal power to quantization noise power* (S/N) at the output of the quantizer will be (Lathi 1998):

$$\frac{S}{N} = \frac{\overline{g^2(t)}}{\sigma_\Delta^2} = 3M^2 \frac{\overline{g^2(t)}}{g_p^2} \quad (4)$$

where $\overline{g^2(t)}$ is a time-averaged mean square value, or average power of the input analog signal.

As follows from equation 4, the output S/N is a linear function of the average power of the input signal. Hence, when the average power is rather small for a weak input signal, the output S/N can decrease dramatically. To achieve some advantage in the output SNR a scheme termed *nonuniform quantization* is used. In nonuniform quantization, the step size of the quantizer is reduced for small amplitude values and progressively increased for larger values. Such types of nonuniform quantization can be achieved by first passing the analog signal through a nonlinear device whose transfer characteristics follow the profile of certain compression curves; after that, a uniform quantizer can be used. These nonlinear curves can also be generated by a piecewise linear approximation. When compression is used at the transmitter, expansion has to be used at the receiver. To correctly restore the original analog signal, the nonlinear functions used for compression and expansion must be inverses of each other. This technique of compressing and expanding is known as *companding* (Lathi 1998).

Figure 4: PCM transmission system

Two types of compression laws are accepted as standards: the μ -law and the A-law. In North America, a μ -law type of compression characteristics is used. It is defined by

$$m_o(t) = \frac{\ln(1 + \mu |m_{in}(t)|)}{\ln(1 + \mu)} \times \text{sign}\{m_{in}(t)\} \quad (5)$$

where $m_o(t)$ and $m_{in}(t)$ are the output and input signals to the compressor normalized by their peak values.

In Europe, the A-law compression characteristic is applied, defined as

$$m_o(t) = \begin{cases} \frac{A m_{in}(t)}{1 + \ln A}, & 0 \leq |m_{in}(t)| \leq \frac{1}{A}, \\ \frac{1 + \ln[A |m_{in}(t)|]}{1 + \ln A} \times \text{sign}\{m_{in}(t)\}, & \frac{1}{A} \leq |m_{in}(t)| \leq 1. \end{cases} \quad (6)$$

The two standard laws of equations 5 and 6 are depicted in Figure 5 for different values of the parameters μ and A. Typical values for such parameters are $\mu = 255$ and $A = 87.6$.

The relation of output SNR for companded PCM is given by

$$\frac{S_o}{N_o} = 3a 2^{2n} \quad (7)$$

where $L = 2^n$, $a = (1 + \ln A)^{-2}$ for A-law compression and, $a = [\ln(1 + \mu)]^{-2}$ for μ -law compression.

Differential Pulse Code Modulation

In practice, adjacent samples of an analog signal (voice, for example) are not completely independent. This effect is more marked, considering that in practice most sampling operations are carried out at rates slightly higher than the Nyquist rate. Therefore, adjacent samples taken from an analog signal contain some redundancy. As a consequence, the transmitted bandwidth is wasted when the redundant samples are transmitted. One way to minimize redundancy is to transmit just the difference

between adjacent samples. The amplitude range of the transmitted information is therefore reduced, thus allowing the use of fewer quantization bits. To reduce even further the amplitude range being transmitted, instead of transmitting the difference between current and previous samples, what can be transmitted is the *difference* between the current sample and its predicted value based on the quantized version of previously transmitted samples. Any good prediction scheme will render a prediction value much closer to the value of the current sample than that of the previous sample value. Such method of digital transmission is called *differential pulse code modulation* (DPCM) (Lathi 1998; Couch 2001).

As shown in Lathi (1998), if the number of transmission bits is the same, then the S/N improvement of DPCM over PCM system is $\alpha = g^2(t)/d^2(t)$, where $d(t)$ is the difference between the amplitude value of the current sample and its predicted value based on previous samples; $g^2(t)$ and $d^2(t)$ are the average powers of $g(t)$ and $d(t)$ signals, respectively.

Delta Modulation

The idea of *delta modulation* (DM) is to increase the correlation between adjacent samples by oversampling above the Nyquist rate in order to achieve such a small difference between the current sample value and its predicted value that it can be encoded using only one bit ($L = 2$). Therefore, DM is a version of DPCM in which the difference in signal values, d_n , can be represented by two quantizing levels—namely, $\pm\delta$ —that correspond to positive or negative differences. Actually both DM and DPCM use the *quantized* values of the previously transmitted samples to predict the value of the current sample. This is because the receiver has available only quantized values of previously transmitted samples. The DM transmission system is depicted in Figure 6.

The integrator provides staircase approximation to the analog signal by a step $\pm\delta$, where the sign depends on the d_n sign as depicted in Figure 7.

DM is subject to two types of quantization errors. In one case, when the staircase approximation cannot follow the signal because it is rapidly rising, the so-called slope overload effect, slope overload noise arises (Lathi 1998). In the second case, *granular noise* affects slow varying signals, becoming encoded in an almost square wave

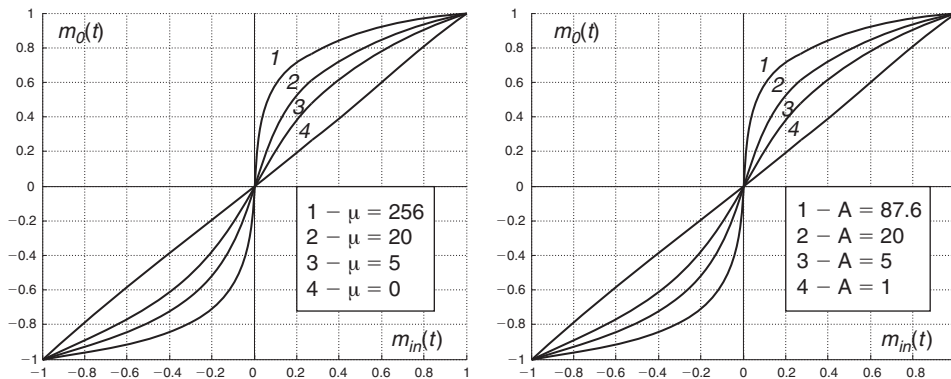

Figure 5: μ - and A-compression laws

Figure 6: DSM transmission system

Figure 7: Regions where slope overload and granular noise occur

fashion. As follows from Figure 7, to avoid slope overload, the staircase slope must be equal to or greater than the maximum analog signal slope; that is,

$$\delta/T_s^{DM} \geq \left(\frac{dg(t)}{dt} \right)_{\max} \quad (8)$$

As shown in Couch (2001), for a voice frequency (VF) signal to avoid overload noise the corresponding value δ should be

$$\delta \geq \frac{1600\pi g_p}{f_s^{DM}} \quad (9)$$

where g_p is a peak value of $g(t)$ and $f_s^{DM} = 1/T_s^{DM}$ is the oversampling rate being used.

The output S/N for a DM system that operates with VF signals can be written in the form

$$\frac{S_o}{N_o} = 2 \frac{3(f_s^{DM})^3}{(1600\pi)^2 B} \times \frac{\overline{g^2(t)}}{g_p^2} \quad (10)$$

The main attractions of DM are simplicity and low cost, although with the decline in price for digital components the low-cost advantage is probably no longer relevant. Note that delta modulation is inferior to PCM for high SNR cases.

Channel Bandwidth for PCM, DPCM, and DM

To find the transmitted bandwidth for PCM, we recall that PCM allows transmitting information at a bit rate given by

$$R_b = 1/T_b = \frac{1}{T_s/n} = nf_s = 2nB \quad (11)$$

As follows from the sampling theorem, $2B$ samples can be transmitted per second per Hz over a channel of bandwidth B Hz. Because each $2B$ sample is quantized and thus encoded into n bits, we need to send $2nB$ pieces of information per second; therefore, the minimum transmission bandwidth will be half that value, or

$$B_{Tmin} = nB = R_b/2 \quad (12)$$

Writing n as B_{Tmin}/B in equation 12 and substituting it in equation 7 yields

$$\frac{S_o}{N_o} = \alpha 2^{2(B_{Tmin}/B)} \quad (13)$$

This means that SNR can be controlled by the transmission bandwidth. It follows from equation 13 that to increase the SNR linearly when using PCM, the transmission bandwidth needs only to be increased logarithmically.

The transmission bandwidth required by DPCM is reduced, compared with PCM, by the coefficient $\beta = n_{PCM}/n_{DPCM}$, where n_{PCM} and n_{DPCM} are the number of bits required for the transmission of the same analog signal at the same output SNR using PCM and DPCM, respectively.

Because the output of a DM transmission system only has one bit, the transmission bit rate of the DM system is $R_b = f_s^{DM}$. Hence, the minimum transmitted bandwidth required for delta modulation is $B_{Tmin} = f_s^{DM}/2$.

Line Coding

Line coding or *transmission coding* is the process of coding our information bits (0's and 1's) into electrical pulses (waveforms) in order to transmit them over a channel. Several signal formats that can be used.

Various types of line coding can be designed, depending on different applications as well as different channel characteristics (LoCicero and Patel 1999). There are two major categories of line codes: return to zero (RZ) and non-return to zero. In RZ coding, the level of the pulse returns to zero during the bit interval. In *non-return to zero* (NRZ) coding, the level of the pulse during the entire bit interval does not change. Line coding formats can also be classified according to the polarity of the voltage levels used to represent the data. For example, in unipolar signaling, the zero level and only one polarity—either positive or negative—is used. In polar signaling, both positive and negative voltage levels are used. In bipolar signaling, positive, negative, and zero voltage levels are used. The most important features that are considered when choosing a line code are the following seven.

1. *Timing.* Line codes should contain enough timing information for synchronization with the transmitter.
2. *Transmission bandwidth.* The bandwidth should be as small as possible.
3. *Probability of error.* The detection error probability should be as small as possible for a given transmission bandwidth and power.
4. *Transparency.* For every possible data sequence, the coded signal can be decoded without problems at the receiver. Note that long strings of 0's or 1's can give synchronization problems in some codes.

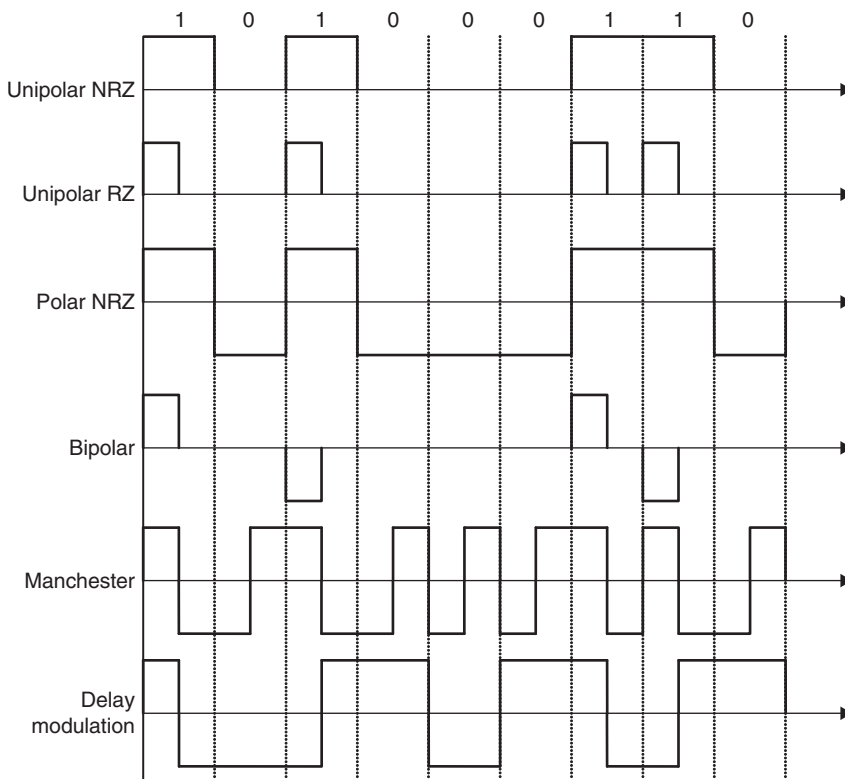

Figure 8: Line coding formats

5. *Memory.* If the current waveform depends on past binary data, then the code is said to have memory; otherwise, the code is memoryless.
6. *Adequate power spectral density profile.* Because AC coupling is used at repeaters, the line code power spectral density should not have a DC component.
7. *Error detection and correction capabilities.* The line code should lend itself to some method of error correction and, if possible, error detection.

The more widely used line coding formats are the following (see Couch 2001; LoCicero and Patel 1999; Haykin 2000): unipolar NRZ (binary on-off keying), unipolar RZ, polar NRZ, polar RZ (alternate mark inversion, or AMI), Manchester coding, delay modulation (Miller code), binary n zero substitution (BNZS), and high-density bipolar n (HDBN). The above line coding formats are depicted in Figure 8 for the binary input data: 101000110.

Unipolar NRZ (Binary On-Off Keying). In unipolar NRZ line code, a binary 1 is represented by a nonzero voltage level, and a binary 0 is represented by a zero voltage level. This is a memoryless code. The major advantages of unipolar NRZ are ease of generation and a relatively small bandwidth of R_b Hz. There are a few disadvantages with this line code: A loss of synchronization can result with a long sequence of 1's or 0's, the code has no error-detection capability, there is a significant DC component, and the error-rate performance is not as good as that of polar line codes.

Unipolar RZ. In unipolar RZ line code, a binary 1 is represented by a nonzero voltage level during one-half of the

bit period. A binary 0 is represented by a zero voltage level during the entire bit duration. This is a memoryless code.

The main advantages of unipolar RZ are ease of generation and the presence of a discrete spectral component at the symbol rate, which allows for straightforward timing recovery. The code's disadvantages are that it has a nonzero DC component, which can lead to DC wander and that a long string of 0's will lead to loss of synchronization; there is no error-detection capability; the bandwidth requirement is $2R_b$ Hz, which is higher than that of NRZ signals; and the bit error-rate performance is worse than that of polar line codes.

Polar NRZ. In polar NRZ line code, a binary 1 is represented by a positive voltage and a binary 0 is represented by a negative voltage over the full bit period. This is a memoryless code. The advantages of polar NRZ include a low-bandwidth requirement of R_b Hz, good error probability, and a zero DC component. Some of the disadvantages include no error-detection capability and long strings of 1's or 0's potentially resulting in loss of synchronization.

Bipolar (Alternate Mark Inversion, or AMI)

In the bipolar or AMI scheme, a binary 1 is represented by alternating the positive and negative voltage levels, which return to zero for one-half of the bit period; a binary 0 is represented by a zero voltage level during the entire bit duration. This is a level code with memory. The AMI code is widely used in telephony. It has no DC component and completely avoids the DC wander problem. This code has error-detection capabilities and a low-bandwidth requirement of R_b Hz. Some of the AMI's codes disadvantages

are a bit error-rate performance that is worse than that of the unipolar and polar waveforms and possible loss of synchronization from long strings of 0's.

Manchester Coding. In the Manchester code, a binary 1 is represented by two mid-bits with positive voltage of the first mid-bit and negative voltage of the second mid-bit. A binary 0 is represented as the exact opposite of a binary 1. A negative or positive mid-bit transition indicates a binary 1 or binary 0, respectively. It has no memory. This line code is used in Ethernet local area networks (LANs). The advantages of this code include zero DC content, ease of timing information extraction, and a bit error-rate performance identical to polar NRZ. The code's main disadvantages are a larger bandwidth than any of the other regular codes and no error-detection capability.

Delay Modulation (Miller Code). In the delay modulation or Miller line code, a binary 1 is represented by a transition at the mid-bit pulse, and a binary 0 is represented by transition of the whole bit duration pulse. A 0 followed by another 0 changes signal polarity. Delay modulation is a transition code with memory. Some of the advantages of this code are that despite no distinct spectral null within the $2R_b$ Hz band, most of the energy is contained in less than $0.5R_b$ Hz, it shows low DC content, it provides good timing content, and it has a bit error-rate performance that is comparable to the other polar line code. One important disadvantage is that it has no error-detection capability.

Binary N Zero Substitution (BNZS). The AMI code has many desirable properties of a line code. Its major limitation, however, is that a long string of zeros can lead to loss of synchronization and timing jitter. The *binary N zero substitution* (BNZS) attempts to improve AMI by substituting a special code of length N for all strings of N zeros in order to maintain the synchronization ability. Furthermore, the special code is chosen in such a way that the desirable properties of AMI coding are retained—that is, DC balance and error-detection capability. BNZS codes require memory. Three common BNZS codes are used: B6ZS, B3ZS, and B8ZS.

In a B6ZS code, a stream of six consecutive zeros is replaced by one of the two special codes according to the rule: If the last pulse was positive (+), then the special code is: 0 + - 0 - +. If the last pulse was negative (-), then the special code is: 0 - + 0 + -. Here a zero indicates a zero voltage level for the bit period, a plus designates a positive pulse, and a minus indicates a negative pulse.

There are four pulses introduced in order to facilitate timing recovery. The special code causes two AMI pulse violations, one in its second bit position and the other in its fifth bit position. These violations are easily detected at the receiver so it can receive the zeros without losing synchronization.

In a B3ZS code, a stream of three consecutive zeros is replaced by either B0V or 00V, where B denotes a pulse that obeys the rule of the AMI and V denotes a pulse violating the AMI convention. The violation always occurs in the third bit position of the substitution code, so it can be easily detected so that zero replacement can be made at the receiver. B3ZS is used in the digital signal-3 (DS-3) signal interface in North America.

The Table 1 presents the B3ZS substitution rules.

A B8ZS code is similar to the B6ZS code. Here a stream of eight consecutive zeros is replaced by one of two special codes according to the following rule. If the last pulse was positive (+), the special code is 0 0 0 + - 0 - +. If the last pulse was negative (-), the special code is 0 0 0 - + 0 + -. There are two bipolar violations in the special codes—at the fourth and seventh bit positions. The B8ZS code is used to provide transparent channels for the integrated services digital network (ISDN) on T1 lines.

High-Density Bipolar N (HDBN) Line Coding. *High-density bipolar N (HDBN) line coding* is especially similar to the BNZS code. If a stream of $N + 1$ consecutive zeros appears, they are replaced by a special code of length $N + 1$ containing certain AMI violations (to facilitate detection). One specific HDBN code is HDB3. In this code, a stream of four consecutive zeros is replaced by either B00V or 000V. Here the violation always occurs in the fourth bit position so that it can be easily detected and replaced by zero at the receiver. The Table 2 presents the HDB3 substitution rules.

Pulse Shaping: Intersymbol Interference

Transmission of baseband rectangular pulses through a band-limited communication channel causes pulse distortion and, as a consequence, *intersymbol interference* (ISI). The problem occurs because the time-limited pulse has an unlimited spectrum, but because the channel is band-limited, the transmitted pulse spectrum becomes limited as well. As the pulse spectrum becomes band-limited, the rectangular pulse itself becomes distorted and is no longer time-limited. The lack of a time limit for the duration of the pulse causes interference, in the time domain, with adjacent pulses (ISI). So the necessary condition to avoid ISI seems to be the requirement that the pulse to be

Table 1: B3ZS Substitution Rules

Number of B Pulses Since Last Violation	Polarity of Last B Pulse	Substitution Code	Substitution Code Form
Odd	Negative (-)	00-	00V
Odd	Positive (+)	00+	00V
Even	Negative (-)	+0+	B0V
Even	Positive (+)	-0-	B0V

Table 2: HDB3 Substitution Rules

Number of B Pulses Since Last Violation	Polarity of Last B Pulse	Substitution Code	Substitution Code Form
Odd	Negative (−)	000−	000V
Odd	Positive (+)	000+	000V
Even	Negative (−)	+00+	B00V
Even	Positive (+)	−00−	B00V

transmitted must have a spectrum that vanishes for frequencies that are outside the channel bandwidth—or, in other words, the pulses should be also band-limited to avoid spectrum mutilation during transmission. The main problem is that a band-limited pulse cannot be simultaneously time-limited. Therefore, it is clear that intersymbol interference is a problem inherent to all practical band-limited channels. To avoid ISI, a better technique is needed.

There exists what is known the *Nyquist criterion for zero ISI*. The pulse-shaping problem to avoid ISI occurrence can be formulated as follows: The appropriate pulse must be synthesized with a compact localization in both time and frequency domains. Furthermore, to avoid affecting adjacent pulses, the transmitted pulse has to be adjusted so that it has nonzero amplitude at its center and zero amplitude at all other signaling instants (adjacent pulses center) (Lathi 1998):

$$g(t) = \begin{cases} 1, & t = 0 \\ 0, & t = \pm nT_b \end{cases} \quad (14)$$

The pulse $p(t) = \text{sinc}(\pi R_b t)$, where $R_b = 1/T_b$ and T_b is the bit period, is the only one that satisfies the previous requirements. It has a compact bandwidth of $R_b/2$ and satisfies the above criteria to avoid ISI (Figure 9). However, this sinc-type shape has two practical inconveniences. The pulse starts at $-\infty$ and therefore it is impractical; furthermore, if it were to be truncated in time, its bandwidth would increase beyond the stated value of $R_b/2$ Hz. On top of this problem, this pulse decays so slowly, at a rate of $1/t$, that the synchronization of the clock in the receiver sampling circuit must be absolutely perfect to avoid the

**Figure 9:** Sinc-type waveforms

ISI that would occur because of any deviation from the exact sampling instant. Unfortunately, it is known that, in practice, sampling instants deviate because of pulse time jitter. As a result of the slow pulse decay, the cumulative effect of the interference from remaining pulses amounts to a large value. There are other reasons for these types of deviations from the exact sampling instants such as little change in the data rate R_b at the transmitter and little change in the sampling rate at the receiver.

Because of these problems, Nyquist considered other pulse shapes that have a slightly wider bandwidth. The idea is to find pulse shapes that go through zero at adjacent sampling points and yet have an envelope that decays much faster than $1/t$. One solution is to generate the pulse as the impulse response of the raised cosine-roll-off Nyquist filter with the frequency transfer function (Couch 2001):

$$G(f) = \begin{cases} 1, & |f| < f_1 \\ 0.5 \left[1 + \cos \left[\frac{\pi |f| - f_1}{2 \Delta f} \right] \right], & f_1 < |f| < B_T \\ 0, & |f| > B_T \end{cases} \quad (15)$$

where $\Delta f = B_T - R_b/2$, and $f_1 = R_b/2 - \Delta f$.

The ratio $r = 2\Delta f/R_b$ is called the roll-off factor. Figure 10 shows the pulse in question as the impulse response of the raised cosine-rolloff Nyquist filter and the frequency transfer function of this filter for the bit rate $R_b = 20$ Hz and three roll-off factors, $r = 0$, $r = 0.5$, and $r = 1$.

Because $0 < r < 1$, the transmission bandwidth varies from $R_b/2$ to R_b , depending on the choice of r ; for any r , it can be calculated as $B_T = (1 + r)R_b/2$. A higher r gives a higher transmission bandwidth. The pulse decays quickly as $1/t^3$ and therefore this type of pulse is less sensitive to small deviations in bit rate, sampling rate, timing jitter, and the like. Hence, the clock timing requirements can now be relaxed.

At this point, the filter is not yet a causal filter. Non-causal filters are not physically realizable. Causal filters have impulse responses that are zero for negative time. Therefore, this filter can be made approximately causal by delaying its impulse response by an appropriate amount of time, t_0 . Such delay causes the peak of the impulse response to move to the right along the time axis. The anticausal tail becomes negligible because of the large order of decay ($1/t^3$) of the filter impulse response.

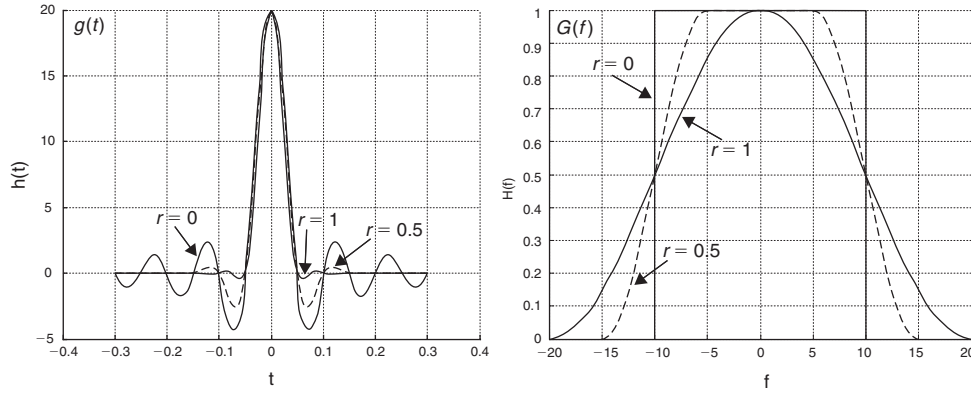

Figure 10: The raised cosine roll-off Nyquist filter characteristics—(a) impulse response (b) spectral characteristics

The introduced time delay leads to a filter with transfer characteristics $G(f)e^{-j\omega t_0}$.

Timing Extraction and Jitter

As mentioned above, to avoid ISI, the clock in the receiver must be synchronized perfectly with the transmitter clock. This requires the transmission of some type of clock signal to maintain timing information. This clock synchronization signal must have a precise frequency and phase relationship with respect to the received input signal. As usual, the synchronization is derived either directly from the input signal (self-synchronization) or from a separate channel that is used only to transmit the synchronization information (pilot clock). A third method would be to have both, with the transmitter and receiver to abide by an independent master timing source. Deriving the synchronization information directly from the incoming signal is more desirable, but the complexity of the bit synchronizer circuit depends on the timing properties of the applied line code. For example, the PSD of BNZS code has a delta function at the frequency that coincides with the bit rate—that is, $f = R_b$. Hence, the bit synchronization clock signal can be extracted by passing the received BNZS waveform through a narrowband bandpass filter with central frequency R_b Hz.

Timing jitter is caused by variations in sampling instants or pulse positions. Interference, noise, and so on can cause the variation of pulse position in the receiver despite the originally transmitted pulses being exactly located. In these cases, the effect of time jitter occurs randomly. Other types of jitter are pattern dependent (because of various causes); as such, their effects are cumulative down the string of regenerative repeaters placed along the channel.

Time Division Multiplexing and Frequency Division Multiplexing

The use of pulse modulation lends itself to the simultaneous transmission of several signals through the same channel. The idea is to use the common channel on a time-sharing basis—that is, different time slots will be adjudicated to different signals in a certain order. Each signal will transmit one (or various) information pulses in its time slot. It will then wait for the other signals to

use their time slots until it is time to transmit again. Therefore when using *time division multiplexing* (TDM), signals will take turns in time to transmit through the channel. When using this modality, signals are transmitted at the same frequency but use different time slots.

The modality of *frequency division multiplexing* (FDM) also permits the simultaneous transmission of several signals through a common channel of a given bandwidth. Here, however, each signal occupies a different frequency range. The sum of each signal frequency range cannot exceed the available channel bandwidth. When using this modality, signals are transmitted at the same time but using different frequencies.

Digital Passband Transmission

In digital *bandpass transmission*, a carrier waveform $A_c \cos(2\pi f_c t)$ with frequency f_c and amplitude A_c is used to encode the incoming baseband modulating signal, $m(t)$, into a bandpass waveform or modulated signal. This encoding is called *modulation*. The carrier waveform, $A_c \cos(2\pi f_c t)$, is used to shift the spectrum of the original baseband waveform by an amount f_c . Shifting the spectrum to a higher frequency range may allow the binary data to be transmitted over a radio link using an antenna of reasonable dimensions.

The modulation process can involve the variation of the amplitude, frequency, or phase of the sinusoidal carrier in accordance with the incoming data. Thus, there are three basic digital modulation schemes known as *amplitude shift keying* (ASK), *phase shift keying* (PSK), and *frequency shift keying* (FSK) (Haykin 2000). Figure 11 depicts the resulting modulated waveforms when the input binary data are 10110.

If the baseband waveform $m(t)$ is an on-off signal, then multiplication by the carrier produces an ASK signal that can be written as

$$s(t) = \begin{cases} A_c g(t) \cos \omega_c t, & m(t) = 1 \\ 0, & m(t) = 0, \end{cases} \quad 0 \leq t \leq T_b \quad (16)$$

where $g(t)$ is the transmitted pulse shape.

Figure 11: Basic digital carrier modulation waveforms

By definition, this is a *double-sideband suppressed carrier* (DSB-SC) AM signal. The spectrum of the ASK waveform is

$$S(f) = \frac{A_c}{2} [G(f - f_c) + G(f + f_c)] \quad (17)$$

If $m(t)$ is a polar signal, then the corresponding modulated signal is a PSK waveform; that is,

$$s(t) = \begin{cases} A_c g(t) \cos \omega_c t, & m(t) = 1 \\ A_c g(t) \cos(\omega_c t - \pi), & m(t) = 0 \end{cases} \quad (18)$$

Here a binary 1 in the baseband stream corresponds to the phase 0 in the bandpass waveform, and a binary 0 in the baseband stream corresponds to the phase π in the bandpass waveform. The PSK signal has the same double-sideband spectral characteristic as the ASK signal.

When the carrier frequency is changing according to a binary data stream, the modulation is called *frequency shift keying* (FSK). Binary FSK modulated signals are written as

$$s(t) = \begin{cases} A_c g(t) \cos 2\pi f_1 t, & m(t) = 1, \\ A_c g(t) \cos 2\pi f_2 t, & m(t) = 0, \end{cases} \quad 0 \leq t \leq T_b \quad (19)$$

The spectrum of FSK may be visualized as the linear superposition of two interleaved ASK signals with frequencies f_1 and f_2 .

Digital Transmission Systems: Noise and Detection Error

Suppose a stream of baseband binary information is being transmitted through an *additive white Gaussian noise* (AWGN) channel. As a consequence, the received signal will contain the desired signal, $g(t)$, plus additive white

Figure 12: The received signal corrupted by noise

Gaussian noise, $n(t)$, as shown in Figure 12 for polar signaling, where $+g(t)$ corresponds to a transmitted binary 1 and $-g(t)$ corresponds to binary 0.

The decision about what pulse was transmitted is done at discrete values of time, $t_k, k = 1, 2, 3, \dots$. It is reasonable for polar transmission to assign a detection threshold equal to zero (Lathi 1998). In other words, despite the additive noise, if the pulse amplitude value at the sampling instant t_k is positive, a 1 was received. If the pulse amplitude at the sampling instant is negative, a 0 was received. The AWGN is a random process with Gaussian *probability density function* (PDF) that will influence the detection decision at the output of the receiver. The probability of making the correct decision, or the probability of no error, is the probability of receiving a 1 (or 0) given that a 1 (or 0) was transmitted, which is $P(1|1) = P(A + n > 0)$ and $P(0|0) = P(-A + n < 0)$. The error occurs when a 0 is detected given that a 1 was transmitted (or vice versa). The probability of error can be written as $P(0|1)$, $P(1|0)$ or, in general, as $P(\epsilon|1) = P(A + n < 0)$, $P(\epsilon|0) = P(-A + n > 0)$. Taking into account that $n(t)$ is a white noise with Gaussian PDF: $p(n) = \left(1/\sqrt{2\pi\sigma_n^2}\right) \exp(-n^2/2\sigma_n^2)$, the probability of error can be calculated as the area under the PDF

when $n > A$ or $n < -A$. Because of the symmetry of the Gaussian PDF, the two areas have the same value—that is,

$$\begin{aligned} P(\epsilon|0) = P(\epsilon|1) &= \frac{1}{\sqrt{2\pi\sigma_n^2}} \int_A^\infty e^{-\frac{n^2}{2\sigma_n^2}} dn \\ &= \frac{1}{\sqrt{2\pi}} \int_{A/\sigma_n}^\infty e^{-\frac{\alpha^2}{2}} d\alpha = Q\left(\frac{A}{\sigma_n}\right) \end{aligned} \quad (20)$$

where $Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-\frac{\alpha^2}{2}} d\alpha$ is a tabulated integral (Lathi 1998).

The average error probability for the polar signaling is $P(e) = 0.5[P(\epsilon|0) + P(\epsilon|1)] = Q(A/\sigma_n)$, where the relation A/σ_n can be viewed as a root square of the SNR, or $S/N = A^2/\sigma_n^2$. For the on-off signaling, the obvious detection threshold is $A_p/2$ and the error probability is $P(\epsilon|1) = P(n > A_p/2)$ or $P(\epsilon|0) = P(n < -A_p/2)$. The average error probability is $P(e) = Q(A/(2\sigma_n))$. For bipolar signaling and assuming thresholds at $A_p/2$ and $-A_p/2$, the average error probability is $P(e) = 1.5Q(A/2\sigma_n)$ (Lathi 1998; Couch 2001; Haykin 2000).

Optimum Threshold Detection

Optimum threshold detection implies maximization of the A/σ_n ratio, which is the argument of the Q function, in order to minimize the average error probability. This leads to the *matched filter* concept. The following discussion can be expanded by reading this material as presented in Lathi (1998). For a received pulse $p(t)$ or $g(t)$, a matched filter maximizes the output S/N at the decision-making instant, and its value is $(S/N)_{\max} = 2E_g/N_0$, where E_g is the energy of the pulse $g(t)$, and N_0 is the *power spectral density* (PSD) of the AWGN. Hence, the minimum probability of error for the detection of this pulse is $P_e = Q(\sqrt{2E_g/N_0})$.

In binary digital communications, two distinct pulses are used. Let's say that pulse corresponds to the transmission of a binary 1 and pulse $q(t)$ corresponds to the transmission of a binary 0. In an optimum binary receiver (see Figure 13), the output at the matched filter stage, at the sampling instant T_b , is a Gaussian random

Figure 14: PDF of the random variable r at the output of the matched filter stage

variable (because of the additive Gaussian noise) of value $r(T_b) = g_o(T_b) + n_o(T_b)$ or $r(T_b) = q_o(T_b) + n_o(T_b)$, depending on which pulse, $g(t)$ or $q(t)$, did arrive. Note that $g_o(T_b)$, $q_o(T_b)$, and $n_o(T_b)$ are output values of the matched filter at sampling instant T_b . The PDF of $r(T_b)$ is depicted in Figure 14.

As shown in Lathi (1998), the bit error probability or *bit error rate* (BER) P_b in this case is $P_b = Q\left(\sqrt{(E_g + E_q - 2E_g E_q)/2N_0}\right)$, where E_g and E_q are the energies of $g(t)$ and $q(t)$, respectively (Lathi 1998). When two distinct pulses are used, the optimum threshold can be found as $o_T = 0.5(E_g - E_q)$. The performance of an optimum receiver in terms of the BER when baseband binary signaling (such as polar, on-off, and bipolar) and bandpass signaling (such as ASK, PSK, and FSK) are used leads to the following relations: $P_b = Q(\sqrt{2E_b/N_0})$

for the polar and PSK cases; $P_b = Q(\sqrt{E_b/N_0})$ for the on-off, FSK coherent detection, and ASK coherent detection cases; and $P_b = 1.5Q(\sqrt{E_b/N_0})$ for the bipolar case. The ASK and FSK can be detected in noncoherent mode, based on envelope detection. The performance is $P_b = (1/2) \exp[-E_b/2N_0]$ for both ASK and FSK (Lathi 1998).

Furthermore, PSK signaling can be detected in differential coherent mode (Couch 2001; Haykin 2000). The resulting modulation is called *differential phase shift keying* (DPSK). The performance of DPSK is $P_b = (1/2) \exp[-E_b/2N_0]$. Figure 15 shows P_b versus E_b/N_0 in dB for different baseband and bandpass binary signaling schemes.

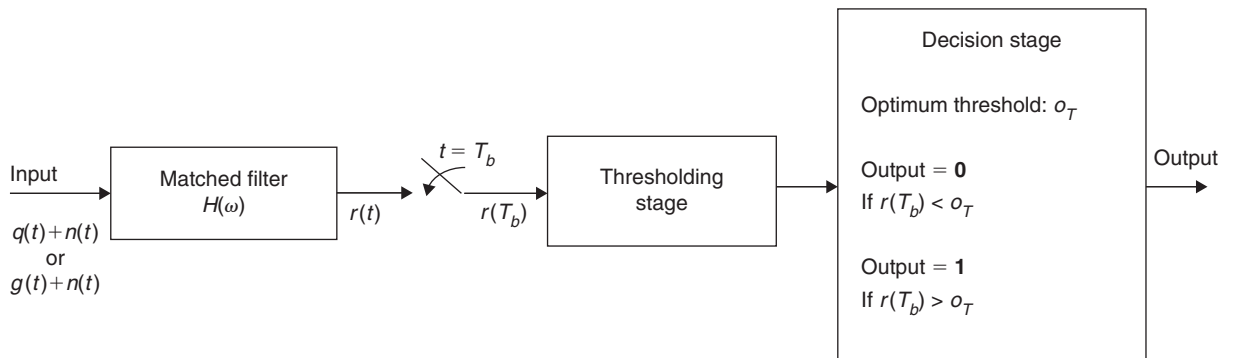

Figure 13: Optimum binary detection system

Figure 16: Converting binary data into M -ary symbols

M-ary Communications

M-ary communications implies the transmission of M symbols instead of two symbols such as in binary signaling. It is commonly used in data communication to achieve higher spectrum efficiency, which is defined as an information rate per unit of band, that is, R/B (Xiong 2000). M -ary symbols are obtained by converting a sequence of $\log_2 M$ binary digits into a corresponding M -ary symbol by *digital-to-analog (D/A) conversion*, as presented in Figure 16. Because a single M -ary symbol carries the information of $\log_2 M$ binary digits, the transmitted power or transmission bandwidth, depending on the case, may have to be increased to keep the same performance level. On the one hand, if several amplitudes are used to distinguish the symbols, then it is clear that signal power will need compensation. On the other hand, if different frequencies are used to differentiate the symbols, then signal bandwidth will have to be increased.

As an example, a four-level signal is presented in Figure 17, where a digital-to-analog converter transforms the binary data into a four different symbols according to the rule $11 \rightarrow +3$, $10 \rightarrow +1$, $00 \rightarrow -1$ and $01 \rightarrow -3$. The resulting symbols form the baseband four-level signal (4-PAM).

When the carrier $A_c \cos 2\pi f_c t$ of frequency f_c and amplitude A_c is used to encode an M -ary baseband signal, any of the following bandpass signaling modes can result: multiphase shift keying, multi-amplitude shift keying, and combined multiphase-multi-amplitude signaling (Proakis and Salehi 2005; Lathi 1998).

Figure 17: The formation of a four-level signal

In *m*-ary phase shift keying (M-PSK) modulation, the information is incorporated on the different phase shifts that affect the carrier. The M possible phases $\theta_k = 2\pi k/M$, $k = 0, 1, \dots, M-1$ are used. The general representation of a set of M carrier phase-modulated signal waveforms is

$$s_k(t) = g(t) \cos(2\pi f_c t + \frac{2\pi k}{M}) = g(t) a_k \cos(2\pi f_c t) - g(t) b_k \sin(2\pi f_c t), k = 0, 2, \dots, M-1, 0 \leq t \leq T \quad (21)$$

where $a_k = \cos \frac{2\pi k}{M}$, $b_k = \sin \frac{2\pi k}{M}$ are the in-phase and quadrature components, respectively, and $g(t)$ is the transmitting filter pulse shape. Therefore, a phase-modulated signal may be viewed as two carriers in quadrature with amplitudes $g(t)a_k$ and $g(t)b_k$.

M-ary quadrature amplitude modulation (M-QAM) is a combined multiphase-multi-amplitude signaling scheme. The transmitted signal has the form

$$s_k(t) = A_k g(t) \cos(2\pi f_c t + \varphi_k) = a_k g(t) \cos(2\pi f_c t) - b_k g(t) \sin(2\pi f_c t), k = 0, 2, \dots, M-1, 0 \leq t \leq T \quad (22)$$

where $a_k = A_k \cos \varphi_k$, $b_k = A_k \sin \varphi_k$, $A_k = \sqrt{a_k^2 + b_k^2}$, $\varphi_k = \tan^{-1}(b_k/a_k)$.

M-QAM multisymbol signaling schemes are generated by letting a_k and b_k take on multiple values. M-QAM may be interpreted as multilevel amplitude modulation that is applied independently on each of the two quadrature carriers.

Sometimes, M-PSK as well as M-QAM signals are represented using two orthonormal basis functions (Proakis and Salehi 2005; Xiong 2000):

$$s_k(t) = s_{kc} \psi_1(t) + s_{ks} \psi_2(t) \quad (23)$$

where $\psi_1(t) = \sqrt{\frac{2}{E_g}} g(t) \cos 2\pi f_c t$ and $\psi_2(t) = -\sqrt{\frac{2}{E_g}} g(t) \sin 2\pi f_c t$ are the orthonormal basis functions and the elements of the vectors are $s_{kc} = \sqrt{\frac{E_g}{2}} a_k$, $s_{ks} = \sqrt{\frac{E_g}{2}} b_k$.

Therefore, both M-PSK and M-QAM signals can be geometrically represented as a two-dimensional vector:

$$\mathbf{s}_k = \left(\sqrt{\frac{E_g}{2}} a_k, \sqrt{\frac{E_g}{2}} b_k \right) \quad (24)$$

Figure 18: The constellation diagram for 8-PSK and 16-QAM

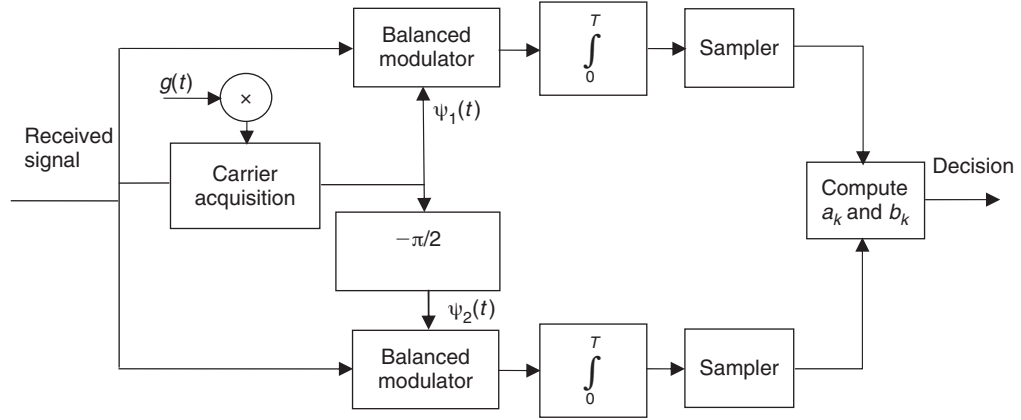

Figure 19: Block diagram of M-PSK and M-QAM transmitter

It is useful to represent the M-PSK and M-QAM signals in a two-dimensional constellation diagram by locating the set of the points $\{a_k, b_k\}$. Figure 18 depicts the constellation diagram for 8-PSK and 16-QAM. As an example, a block diagram of an M-ary bandpass transmitter is presented in Figure 19. The $\log_2 M$ successive binary input pulses are stored and then converted into the pair of numbers (a_k, b_k) that are used to modulate two quadrature carrier terms, $\cos(2\pi f_c t)$ and $\sin(2\pi f_c t)$, respectively. Depending on the values $\{a_k, b_k\}$, the transmitter can be applied either to M-PSK or M-QAM modulation.

The structure of the optimum receiver in the presence of white Gaussian noise for M-PSK (M-QAM) signals is presented in Figure 20 (Proakis and Salehi 2005; Xiong 2000), where the received signal (23), which eventually

includes an additive noisy component, is multiplied by two orthonormal functions $\psi_1(t)$ and $\psi_2(t)$. After the integration and sampling stages, the elements of the received vector are $s_{kc} = \sqrt{\frac{E_g}{2}} a_k$, $s_{ks} = \sqrt{\frac{E_g}{2}} b_k$ if no noise is included.

Pros and Cons of the Different M-ary Communication Techniques

The main advantage of multi-amplitude signaling is the reduction on transmitted bandwidth by a factor of $\log_2 M$ compared with the binary case for the same rate of information transmission. Although the transmission bandwidth is reduced (Lathi 1998; Xiong 2000), the transmission

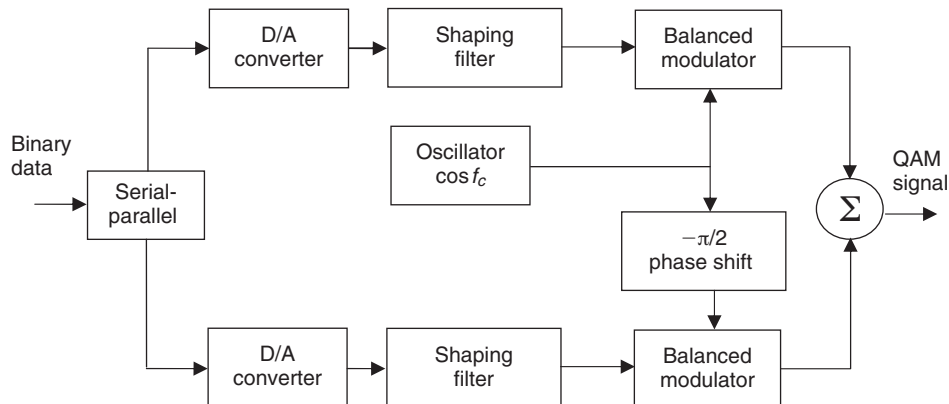

Figure 20: Block diagram of M-PSK and M-QAM optimum receiver

power increases as M^2 , which can be viewed as a trade-off or cost to be paid for the reduction in bandwidth. As we said, when using M-PAM, M-QAM, and M-PSK for a fixed bit rate, the channel bandwidth decreases as the number of signals, M , increase. As M increases, the system increases its bandwidth efficiency (Proakis and Salehi 2005). However, an increase in M also means an increase in error probability (lower performance) that can be compensated by an increase in signal power that, in turn, decreases the power efficiency. Therefore, on the one hand, this brings us to the conclusion that M-ary, M-PAM, M-QAM, and PSK are amenable to bandwidth-limited communication channels such as telephone channels as long as there is enough power to support the multiple signaling phases and amplitudes (Proakis and Salehi 2005). Within this framework, it can also be said that M-QAM is better than M-PSK for large signal constellation sizes. On the other hand, multitone signals (use of different frequencies instead of different amplitudes or phases) are suitable for large bandwidth but power-limited channels (Lathi 1998).

Error Correction and Detection

The transmission of information over a communication link always results in some degradation in the quality of the information because of noise and interferers. In analog links, the degradation is measured in the form of a decrease in signal-to-noise ratio. In digital links, the degradation is measured in terms of the bit error rate. An essential difference between analog and digital transmission is that the quality of a digital signal can be improved by the use of error-correction techniques. In a digital system, some extra redundant bits are added to the data stream that not only can indicate when an error occurs but also point to the particular bit or bits that have been corrupted. Afterward, the communication system can correct the errors that were detected.

Systems that only detect errors (error-detection systems) must make a decision about what action to take when an error is detected: ignore the error, flag the error, send a block of information again, or estimate the error and replace the corrupted data.

Systems that detect and correct errors (e.g., a *forward error correction* or FEC system) generate codes that can detect and correct some errors in a given data stream. The number of errors that can be corrected strongly depends on the number of redundant bits. An increase in the number of redundant bits results in a reduction of the data rate. This is because the redundant bits are not data bits. In practice, there is a trade-off between the number of redundant bits added to the information data bits and the rate at which information is sent over the link.

In some FEC systems, the number of redundant bits is equal to the number of data bits, resulting in a halving of the data rate for a given channel transmission rate. This is called *half-rate FEC*. It has some advantages: It is easier to implement than other rates because it simplifies clock synchronization between the input data stream and the output coded stream.

The most widely used codes in FEC systems are linear block codes, cyclic block codes, and convolutional codes.

Linear block codes are codes in which n -bit code words contain k message bits and $(n - k)$ redundant check bits. A codeword with n bits of which k bits are message data is denoted as (n, k) . In a systematic linear block code, the first k bits of the code word are the message bits, and the remaining $(n - k)$ bits are the parity bits.

A large number of binary cyclic codes have been found, many of which have been named after the people who first proposed them. The best known binary cyclic codes are the *Bose-Chaudhuri-Hocquenghem codes* (BCH), the Reed-Solomon codes, and the Golay codes. For example, the Golay code is a $(23, 12)$ cyclic code that corrects all patterns of three or fewer bit errors.

The performance of FEC systems compared with other systems that do not apply error correction is considerably better. For instance, adding half-rate FEC to the data streams using convolutional coding leads to a roughly 3-dB improvement in *carrier-to-noise ratio* (CNR) at the baseband output of the receiver (Lathi 1998).

Capacity of a Band-Limited AWGN Channel

Channel capacity can be defined as the maximum rate of information transmission that can be achieved over a channel. As a rule, all communication systems involve the use of noisy channels, a fact that reduces the capacity of the overall transmission channel. For an *additive white Gaussian noise* (AWGN) channel, where the additive Gaussian noise is band-limited and zero mean, the capacity C is given by Shannon's law as

$$C = B \times \log_2 \left(1 + \frac{S}{N} \right) \text{ bit/s} \quad (25)$$

where B is the channel bandwidth in Hz, S/N is the received signal-to-noise ratio, and the channel capacity, C , gives the maximum possible information transmitted per second (Lathi 1998).

When the channel bandwidth goes to infinity, $B \rightarrow \infty$, the channel capacity reaches an upper limit. Assuming that $N = N_0 B$, where N_0 is the single-sided noise power spectral density in watts per hertz, the limit can be found (Lathi 1998) to be

$$\lim_{B \rightarrow \infty} C = \lim_{B \rightarrow \infty} B \times \log_2 \left(1 + \frac{S}{N_0 B} \right) = 1.44 \frac{S}{N_0} \quad (26)$$

Equation 26 is known as the *Shannon bound*. It shows that for finite power signals and noise, the channel capacity remains finite in spite of infinite channel bandwidth.

Multiple-Access Techniques

Multiple access permits the resources of a communication system to be shared by a large number of users who are seeking to communicate with each other. In particular, the sharing of available bandwidth has to be accomplished without causing severe interference among users. For example, in a satellite link, many earth stations can access a single satellite transponder from widely different locations at the same time. Another example is cellular

communications: Many mobile handsets can access a base station at the same time.

Some basic types of multiple access techniques can be identified: *frequency division multiple access* (FDMA), *time division multiple access* (TDMA), *code division multiple access* (CDMA), *space division multiple access* (SDMA), and *random access* (RA).

In FDMA, the available frequency band is broken into *sub-bands* that are assigned to different users. To reduce interference between users, *guard bands* are introduced. These guard bands relax filtering requirements as well.

In TDMA, each user is allocated the full available frequency band but only for a short duration of time called a *time slot*. Guard times are inserted between the assigned time slots to reduce interference between users and relax the synchronization requirements.

CDMA includes *direct-sequence CDMA* (DS-CDMA) and *frequency-hopping CDMA* (FH-CDMA). In DS-CDMA, each user is assigned a unique code that distinguishes this user from other users. The assigned code is in the form of a much higher rate *pseudonoise* (PN) sequence of bits (chips) that are used to encode the data bits. The higher chip rate accounts for the spreading of the spectrum. Only those who possess the right PN code can decode the transmission of a particular user.

Each user is allocated the channel's full spectral and temporal occupancy. An important advantage of CDMA over both FDMA and TDMA is that, because of the encoding, it can provide secure communications. In FH-CDMA, for each successive time slot, the frequency bands assigned to users are reordered in a pseudorandom manner.

In SDMA, the spatial separation of earth mobile units is exploited. In particular, multibeam antennas can be used to separate signals by pointing them along different directions. Different mobile users can access the base station simultaneously, at the same frequency, at the same time or even using the same PN code.

CONCLUSION

A brief overview of some techniques used in the area of digital information transmission has been presented. Digital transmission has taken over the field of information transmission, and its further development is continually being fueled by market demand. The current trend is one of permanent falling prices for most digital communication devices and a steady increase in their capabilities and performance. There is no end in sight to this trend except, maybe, for the continuous increase in the component count in integrated circuits, which at some point may reach the current technology miniaturization limits. New technologies, such as nanotechnology, are already on the horizon to help sustain the future growth of this field.

GLOSSARY

Additive white Gaussian noise (AWGN): A random process with Gaussian probability density function that is added to the information signal and as such influences the detection decision at the output of a receiver.

Alternate mark inversion (AMI) code: Pseudoternary signal where no pulse encodes a 0 and a pulse $p(t)$ or $-p(t)$, with consecutive pulses having alternating polarities, encodes a 1. The fact that consecutive 1's are encoded with pulses of alternate sign facilitates error detection.

Amplitude shift keying (ASK): The amplitude of a carrier waveform varies (shift) among two amplitude values (usually A and 0) in order to encode 1's and 0's. If the amplitude shifts among more than two values it is called M-ASK, where M is the number of possible amplitudes.

Analog to digital converter (A/D or ADC): Transforms an analog information waveform into a digital data source.

Bandpass transmission: A type of transmission in which the spectrum of the original information is shifted to a much higher frequency, specifically around the frequency of the carrier waveform.

Baseband transmission: A type of transmission in which the transmitted signal has a spectrum concentrated around frequency $f = 0$.

Binary N zero substitution (BNZS): When N successive 0's are detected, they are suppressed and substituted by a particular sequence of N bits that includes a deliberate bipolar violation that can be easily detected and corrected. This avoids the loss of synchronization caused by too many consecutive 0's. The value of N depends on the standard.

Delta modulation (DM): A form of DPCM in which the difference between the actual sample value and that of the predicted sample value inferred from the previously quantized sample values is encoded using only one bit. The use of only two levels for encoding such a difference is made possible by oversampling, which increases adjacent sample correlation and thus reduces the prediction error.

Differential pulse code modulation (DPCM): A technique by which the difference between the actual sample value and that of the predicted sample value inferred from the previously quantized sample values, is encoded using N bits. The smaller range of the difference, compared to the full sample value provides the following choice: Keep the same number of quantizations bits and improve the SNR or keep the same SNR and decrease the transmission bit rate.

Frequency shift keying (FSK): The frequency carrier waveform is varied (shifted) among a set of prescribed discrete frequency values in order to encode the binary bits.

High-density bipolar N line coding (HDBN): Is a code that when $N + 1$ consecutive zeros appear, the group of zeros is changed by one of certain $N + 1$ digit sequences. To avoid the loss of synchronization caused by a run of several zeros, the replacement sequences are chosen to include some binary 1's to help keep proper timing and deliberately violate the bipolar rule for easy identification.

Intersymbol interference (ISI): Then spreading of a pulse beyond its interval, which causes it to interfere with adjacent and nearby pulses.

Low-pass filter (LPF): Filter that blocks higher frequencies that are beyond a certain cutoff frequency.

M-ary communications: Communication using M symbols.

Matched filter: A filter that maximizes the output S/N at the decision-making instant when the expected symbol arrives at the receiver.

Multiamplitude shift keying (M-ASK): The amplitude of a carrier waveform varies (shifts) among the elements of a discrete set of M previously accorded values in order to encode the binary bits.

Multiphase-multiamplitude quadrature amplitude modulation (M-QAM): The phase and the amplitude of a carrier waveform varies (shifts) among the elements of a discrete set of M previously accorded values in order to encode the binary bits.

Multiphase shift keying (M-PSK): The phase of a carrier waveform varies (shifts) among the elements of a discrete set of M previously accorded values in order to encode the binary bits.

Non-return to zero (NRZ): Line codes using pulses that maintain a nonzero value during the complete bit period; thus, their amplitudes can never “return to zero.”

Phase shift keying (PSK): The phase of a carrier waveform varies (shift) among a discrete set of phase values in order to encode 1's and 0's. In particular, if the phase shifts between two values, it is called BPSK. If the phase shifts among M values, it is called M-PSK.

Power spectral density (PSD): For random processes, it is given by the Fourier transform of the autocorrelation function. It gives an idea of how signal power is allocated with relation to the signal frequency content.

Probability density function (Pdf): For a random variable X the Pdf $f_X(x)$, if it exists, is defined as the derivative of the *cumulative distribution function* (Cdf). The Cdf is the probability of the event $\{X \leq x\}$ —that is, $F_X(x) = P\{X \leq x\}$.

Pulse amplitude modulation (PAM): The amplitude of a pulse is used to encode the value of the sample.

Pulse code modulation (PCM): A system by which an analog signal is sampled at a rate F_s samples per second and then the amplitude of each sample is quantized (adopting one out of L possible values) using N bits. The sampling rate F_s is usually 8000 samples per second, N is 8, and L is 256 for regular telephone communication.

Return to zero (RZ): Line codes using pulses that do not maintain a nonzero value during the complete bit period.

Signal-to-noise ratio (S/N or SNR): Ratio of the power of the information signal to the power of the noise signal that accompanies the information signal.

INTRODUCTION

The main purpose of a communication system is to transmit information through a communication channel between a transmitter and a receiver. In general, the information is converted into a signal that varies in an unpredictable and random manner. These random information-bearing signals are broadly subdivided into two categories: *digital* and *analog*. Digital signals are constructed with a fixed and finite number of possible choices or selections, usually called symbols, and abruptly change from one symbol to another at discrete instants of time. For example, a text is a digital signal constructed from approximately fifty symbols. Analog signals accept any value between given limits and typically vary smoothly and continuously over time. The analog signals are acquired from natural analog sources—for example, the temperature or atmospheric pressure at certain locations (Pierce and Noll 1990).

ANALOG MODULATION

Information-bearing signals can be in the form of *baseband signals*. The term *baseband* refers to the band of frequencies that represents the original signal produced by a source of information. These signals are not always suitable for direct transmission over a given channel. In fact, the appropriate use of the communication channel requires a shift of the range of baseband frequencies into other frequency ranges that are efficient for transmission and a corresponding shift back to the original frequency range after reception. A shift of the range of frequencies in a signal is accomplished using *modulation*, which is defined as the process by which some characteristics of a carrier are varied in accordance with the information-bearing signal. A common form of the carrier

in *analog modulation* is a *sinusoidal wave*. The baseband information-bearing signal is referred to as the *modulating wave*, and the bandpass signal resulting from the modulation process is referred to as the *modulated wave*. Although the modulation process is performed at the transmitter, we usually need the original baseband signal to be restored at the receiver. This is accomplished through a process known as *demodulation*, which is the reverse of the modulation process (Haykin 2001).

The modulation process is performed to achieve one or more of the following objectives (Proakis and Salehi 2002; Ziemer and Tranter 2001):

1. match the baseband signal to the passband characteristics of the channel after translation into a bandpass signal,
2. accommodate for simultaneous transmission of signals from several message sources, and
3. expand the bandwidth of the transmitted signal to increase the noise immunity in a noisy channel.

Frequency multiplexing is an example of the second process. It is commonly used in long-distance telephone transmissions in which many narrowband voice channels are accommodated in a wideband coaxial cable. The bandwidth of such a cable is typically some megahertz, and the bandwidth of each voice channel is approximately 4 kilohertz (kHz). The cable bandwidth is divided into intervals of 4 kHz, and one voice channel is transmitted in each interval. Therefore, each voice channel must be processed (modulated) in order to shift its spectrum into the appropriate frequency slot. At the receiver, the reverse process of demodulation is necessary.

Basically, the transmitter of an analog communication system consists of a modulator and the receiver consists

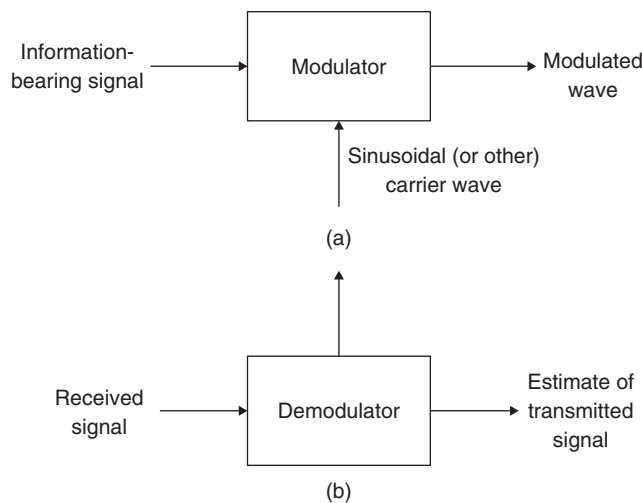

Figure 1: Basic elements of a continuous-wave communication system: (a) transmitter, (b) receiver

of a demodulator, as shown in Figure 1. In addition to the modulated wave, the received signal in the demodulator includes channel noise and distortion. Therefore, the performance of the communication system in the presence of these degradations depends on the type of the modulating wave and the employed modulation scheme. Typically in a communication system, the analog signals are converted into digital signals via sampling and quantization, because digital signals can be made more immune to noise (Ziemer and Tranter 2001; Lathi 1998).

Analog Modulation versus Pulse Modulation

In analog modulation, some parameters of a sinusoidal carrier wave are varied in accordance with the information-bearing signal. These parameters are *amplitude*, *frequency*, or *phase* of the sinusoidal carrier wave. Depending on the type of the modulating wave, these variations will result in a certain kind of modulation as follows (Haykin 2001);

- For an analog signal, these continuous variations may result in *amplitude modulation* (AM), *frequency modulation* (FM), or *phase modulation* (PM), respectively.
- For a digital binary signal, these discrete variations may result in *amplitude shift keying* (ASK), *frequency shift keying* (FSK), or *phase shift keying* (PSK), respectively.

In contrast to analog modulation, in *pulse modulation* some parameters of a pulse train are varied in accordance with the information-bearing signal. Again, depending on the type of transmission signal, there are two families of pulse modulation: *analog pulse modulation* and *digital pulse modulation*, as follows (Haykin 2001; Gagliardi 1988);

- In analog pulse modulation, a periodic pulse train is used as the carrier wave, and some features of each pulse—for example, amplitude, duration, or position—are continuously varied in accordance with the corresponding sample value of the signal. These variations result in *pulse amplitude modulation* (PAM), *pulse duration*

modulation (PDM), or *pulse position modulation* (PPM), respectively.

- In digital pulse modulation, the signal is represented in a form that is discrete in both time and amplitude. Therefore, the transmission takes place in digital form as a sequence of *coded pulses*.

Analog transmission requires high frequency circuitry, but it is known to have the following advantages over digital transmission (Lathi 1998):

- flexible frequency band allocation for different sources,
- suitability for wireless transmission where the signal frequency needs to be sufficiently high for antenna length restriction,
- amenability to band-limited electronic devices.

In general, the choice of modulation depends on several factors (Haykin 2001; Proakis and Salehi 2002):

- the characteristics of the information-bearing signal;
- the channel characteristics, such as the type of the transmission medium and the type of channel disturbances;
- performance requirements; and
- economic factors in practical implementations.

In this chapter, we study analog-modulation systems for both analog and digital signals in a noise-free environment. Real communication is always accompanied by noise; however, the objective of this chapter is to represent basic ideas of analog modulation.

Noise in Analog Transmission

The term *noise* is usually used to refer to unwanted signals that tend to disturb the transmission and processing of signals in communication systems and over which we have incomplete control. In the design of communication systems for transmitting information through physical channels, it is convenient to construct mathematical models that reflect the most important characteristics of the transmission medium (Haykin 2001; Proakis and Salehi 2002).

The simplest mathematical model for a communication channel is the additive noise channel as illustrated in Figure 2. In this model, the transmitted signal, $s(t)$, is corrupted by an additive random noise process, $n(t)$. Physically, the additive noise process arises from electronic components and amplifiers at the receiver of the communication system or from interference caused in transmission. If the noise is introduced primarily by electronic components and amplifiers at the receiver, then it may be characterized as *thermal noise*. This type of noise is statistically characterized as a *Gaussian noise process*.

Figure 2: The additive noise channel

Therefore, the resulting mathematical model for the channel is usually called the *additive Gaussian noise channel* or *additive white Gaussian noise (AWGN) channel* if the noise is wideband with a constant spectral density (expressed as watts per hertz of bandwidth). This model does not account for the phenomena of fading, frequency selectivity, interference, nonlinearity, or dispersion. However, it produces simple and tractable mathematical models that are useful for gaining insight into the underlying behavior of a system before these other phenomena are considered. The AWGN channel is a good model for many satellite and deep space communication links. It is not a good model for most terrestrial links because of multipath, terrain blocking, interference, and so on. However, for terrestrial path modeling, AWGN is commonly used to simulate background noise of the channel under study in addition to the multipath, terrain blocking, interference, ground clutter, and self-interference that modern radio systems encounter in terrestrial operation (Ziemer and Tranter 2001; Wikipedia 2007; Downing 1964; Schwartz 1980).

ANALOG MODULATION FOR ANALOG SIGNALS

The general expression for a sinusoidal carrier is

$$c(t) = A_c \cos(2\pi f_c t + \phi_c) \quad (1)$$

where A_c , f_c , and ϕ_c are amplitude, frequency, and phase of the carrier signal, respectively. These three parameters may be varied for the purpose of transmitting an information-bearing analog signal $m(t)$ to result in amplitude, frequency, and phase modulation, respectively. In effect, the modulation process converts the signal $m(t)$ from baseband to produce a bandpass signal in the neighborhood of the center frequency, f_c . Figure 3 displays the waveforms of amplitude-modulated and frequency-modulated signals for the case of sinusoidal modulation and a single-tone

Figure 3: AM and FM signals produced by a single tone; (a) carrier wave $c(t)$; (b) sinusoidal modulating signal $m(t)$; (c) amplitude modulation; (d) angle (frequency) modulation

modulating waveform. This figure clearly explains the major differences between amplitude modulation and frequency or phase modulation. In fact, frequency modulation and phase modulation are both special cases of *angle modulation*. Basically, in this case, the only difference between frequency modulation and phase modulation is a phase shift in the modulated signal.

AMPLITUDE MODULATION

As noted above, in *amplitude modulation (AM)*, the message signal $m(t)$ affects the amplitude of the carrier signal, $c(t)$. There are four main implementation methods for AM: double-sideband AM (DSB AM), double-sideband suppressed carrier AM (DSB-SC AM), single-sideband AM (SSB AM), and vestigial sideband AM (VSB AM).

Double-Sideband Amplitude Modulation

In *double-sideband amplitude modulation (DSB AM)*, the carrier amplitude is proportional to the instantaneous amplitude of the modulating signal

$$s(t) = [1 + m(t)]c(t) = A_c[1 + m(t)] \cos(2\pi f_c t + \phi_c) \quad (2)$$

In practice $|m(t)| \leq 1$ so that $A_c[1 + m(t)] \geq 0$ for an undistorted envelope and easy demodulation. If this condition is not satisfied, the AM signal is said to be *overmodulated*, and its demodulator hardware becomes more complex (Haykin 2001).

Although, in practice, the message signal $m(t)$ is unknown, here we consider a deterministic signal. In such a case, the spectrum of the AM signal $s(t)$ is

$$\begin{aligned} S(f) &= \mathcal{F}[m(t)] \otimes \mathcal{F}[A_c \cos(2\pi f_c t + \phi_c)] \\ &\quad + \mathcal{F}[A_c \cos(2\pi f_c t + \phi_c)] \\ &= \frac{A_c}{2} \left[e^{j\phi_c} M(f - f_c) + e^{j\phi_c} \delta(f - f_c) + e^{-j\phi_c} \right. \\ &\quad \left. M(f + f_c) + e^{-j\phi_c} \delta(f + f_c) \right] \end{aligned} \quad (3)$$

where $M(f)$ represents the Fourier spectrum of $m(t)$ —that is, $m(t) \xleftrightarrow{\mathcal{F}} M(f)$, and \mathcal{F} , \otimes , and $\delta(\cdot)$ denote the Fourier transform, the convolution, and the Dirac delta function, respectively. Figure 4 illustrates such an AM signal in both time and frequency domains as well as the basic structure of modulator when the input signal is fed as $1 + m(t)$. We observe that the spectrum of a DSB AM signal occupies a bandwidth that is twice the bandwidth of the message signal W . In fact, the magnitude of the spectrum of the message signal, $m(t)$, is translated or shifted in frequency by an amount of f_c . The phase of the message signal is also translated to the same frequency and offset by the carrier phase, ϕ_c , which is not shown in this figure. The frequency contents of the modulated signal $S(f)$ in the frequency band $|f| > f_c$ is called the *upper sideband (USB)* of $S(f)$, and the frequency content in the frequency band $|f| < f_c$ is called the *lower sideband (LSB)* of $S(f)$. Note that either one of the sidebands of $S(f)$ contains all the frequencies that exist in $M(f)$, therefore it is called a *double-sideband (DSB) AM* signal (Shanmugan 1979; Couch 2001).

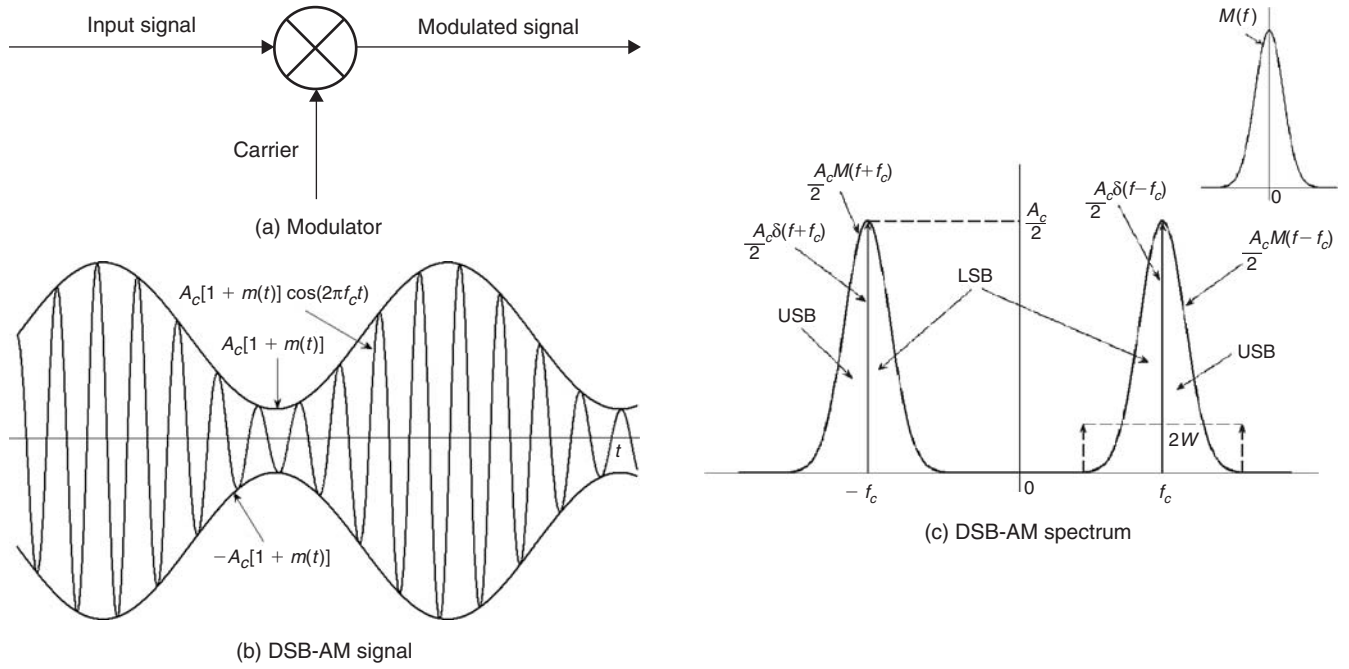

Figure 4: DSB AM signal and its spectrum

As stated above, $|m(t)| \leq 1$ is a necessary condition to have an easy demodulation for the DSB AM signal (see Figure 4b). In this case, the envelope has the same shape as $m(t)$ (although riding on a *direct current*, DC), and therefore it is possible to detect the desired signal $m(t)$ by using a simple envelope detection. Otherwise, we have to employ other demodulation techniques that require generation of a local carrier for the demodulation. Thus, the condition for envelope detection of an AM signal is $1 + m(t) \geq 0$, for all t (Haykin 2001; Proakis and Salehi 2002).

It is sometimes convenient to express $m(t)$ as $m(t) = \beta m_n(t)$ where $m_n(t)$ is normalized such that its minimum value is -1 ; the scalar factor β is called the *modulation index*. The modulation index or modulation depth indicates how much the modulated variable varies around its original level. Using this factor, the *modulation efficiency* of a DSB AM signal is defined as the ratio of the power in the modulated signal that contributes to the transmission of the message to the total power in the modulated signal; this is given by

$$\eta = \frac{\beta^2 P_{m_n}}{1 + \beta^2 P_{m_n}} \quad (4)$$

where P_{m_n} is the power in $m_n(t)$ (Proakis and Salehi 2002). As an example for the special case of tone modulation, we have $\eta = \frac{\beta^2}{2 + \beta^2}$ with the condition that $0 \leq \beta \leq 1$. In

this case, the modulation efficiency η takes its maximum of 33 percent in the best condition when $\beta = 1$. In practical situations and for the case of envelope detection ($|m(t)| \leq 1$), this efficiency is usually lower than 25 percent.

This is the price that must be paid for the advantage of envelope detection in AM (Haykin 2001; Lathi 1998).

Generation of DSB AM signals

DSB AM is produced by multiplying together the carrier and the input signal $1 + m(t)$ as depicted in Figure 4a. The multiplication can be achieved using a network with a nonlinear behavior—for example, a diode modulator (as shown in Figure 5). The input/output characteristics of this circuit are written in terms of a power series:

$$V_{out} = aV_{in} + bV_{in}^2 + cV_{in}^3 + \dots \quad (5)$$

If $V_{in} = A_c \cos 2\pi f_c t + m(t)$, then the output is given by

$$V_{out} = A_c \cos(2\pi f_c t)[a + b_m(t)] + \text{other terms} \quad (6)$$

As “other terms” are higher frequency components that are easily filtered off, the diode produces the required modulation.

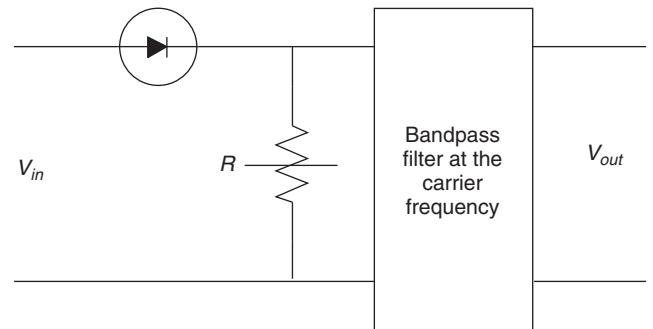

Figure 5: Diode modulator to generate DSB AM

Another method to generate AM signals is to employ a switching modulator; this is explained in Lathi (1998).

Demodulation of DSB AM Signals

The *detection* (i.e., *demodulation*) of DSB AM can be broadly considered under two headings: noncoherent and coherent. Traditionally, broadcast receivers use envelope detection. With the advent of the integrated *phase-locked loop* (PLL), coherent detectors are now attractive. The envelope (noncoherent) detector physically reproduces the envelope of the modulated carrier. The detector is basically a half-wave rectifier that commonly makes use of a silicon diode and a *low-pass filter* (LPF) as shown in Figure 6a.

When $|m(t)| \leq 1$, the rectifier eliminates the negative part of the modulated signal without affecting the message signal. In other words, the rectified signal is equal to $s(t)$ when $s(t) > 0$ and zero when $s(t) < 0$. The message signal is recovered by passing the rectified signal through an LPF whose bandwidth matches that of the message signal. The combination of the rectifier and the LPF is called an *envelope detector*. Ideally, the output of this detector is in the form of $a + bm(t)$, where a represents a DC component and b is a gain factor resulting from the signal modulator. The DC component can be eliminated by passing $d(t)$ through a transformer whose output is then $bm(t)$. The operation of an envelope detector in the presence of a square-wave message signal is shown in Figure 6b (Haykin 2001; Proakis and Salehi 2002).

Double-Sideband Suppressed Carrier Amplitude Modulation

The total power transmitted in a DSB AM signal is the sum of the carrier power and the total power in the sidebands.

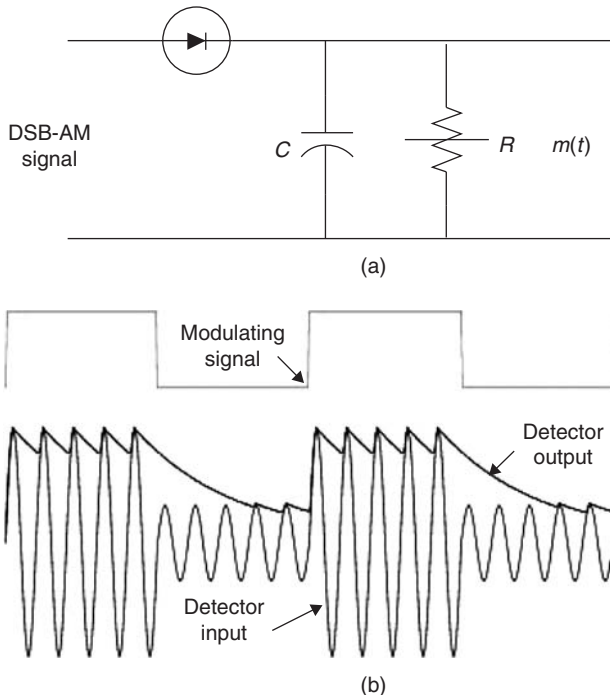

Figure 6: Envelope detector for DSB AM

If the modulating signal is a single tone, then the modulation efficiency based on equation 4 is 33 percent in the best situation. If the carrier can be suppressed, or at least reduced in amplitude, then practically all of the transmitted power is used for signal. This is more important when the received signal is distorted by noise because it produces a higher effective *signal-to-noise ratio* (SNR) than when the full carrier is transmitted. This motivates us to propose a new AM scheme called *double-sideband suppressed carrier* (DSB-SC) AM. The price paid for removing the carrier is an increase in the complexity of the detector (Lathi 1998).

The DSB-SC AM signal is obtained by multiplying the message signal $m(t)$ with the carrier signal $c(t)$ as follows

$$s(t) = m(t) c(t) = A_c m(t) \cos(2\pi f_c t + \phi_c) \quad (7)$$

The spectrum of this modulated AM signal $s(t)$ is given by

$$\begin{aligned} S(f) &= \mathcal{F}[m(t)] \otimes \mathcal{F}[A_c \cos(2\pi f_c t + \phi_c)] \\ &= \frac{A_c}{2} [e^{j\phi_c} M(f - f_c) + e^{-j\phi_c} M(f + f_c)] \end{aligned} \quad (8)$$

and is shown in Figure 7, where $M(f)$ represents the Fourier spectrum of $m(t)$ and $M(0) = M(f)|_{f=0}$. This spectrum is similar to what is shown for DSB AM in Figure 4, except for the Dirac delta functions used to illustrate the existence of carrier $A_c \cos(2\pi f_c t)$ in the modulated signal. For this reason, the signal resulting from this modulation is called *suppressed carrier signal*. In addition, the structure of the DSB-SC AM modulator is basically the same as the one proposed in Figure 4; it uses the proper input signal $m(t)$, which is the modulating signal in this case. Similar to the case of DSB AM, it is to be noted that the bandwidth occupancy of DSB-SC AM is $2W$ when the bandwidth of the message signal is assumed to be W .

Generation of DSB-SC AM signals

Modulation of DSB-SC AM is achieved in several ways. Important modulators include multiplier modulators, nonlinear modulators, and switching modulators (Couch 2001). All of these techniques are simply different methods of implementing the multiplication operation shown in Figure 4a by different methods: Multiplier modulators take advantage of analog multipliers, nonlinear modulators use nonlinear devices (e.g., see Figure 5), and switching

Figure 7: DSB-SC AM spectrum

Figure 8: Nonlinear modulator to generate DSB-SC AM

modulators employ a simple switching operation. Here we explain nonlinear modulators in more detail.

As previously stated, modulation can be achieved by using nonlinear devices such as semiconductor diodes or transistors. Figure 8 depicts one possible scheme that uses two identical nonlinear elements. If the input/output characteristics of the nonlinear elements are represented by the same relationship as in equation 5, then the signal $z(t)$ is represented by

$$z(t) = 2am(t) + 4bm(t)A_c \cos 2\pi f_c t + \text{other terms} \quad (9)$$

Whereas the spectrum of $m(t) \cos 2\pi f_c t$ is centered at the carrier frequency, if $m(t)$ and “other terms” are filtered off properly through the *bandpass filter* (BPF), the proposed structure produces the desired modulated signal. This structure is called a *single balanced modulator* (Proakis and Salehi 2002; Lathi 1998).

Demodulation of DSB-SC AM Signals

This type of modulation requires coherent detection. Because no tone component with the frequency f_c is transmitted, the required component must be generated through a local oscillator. Special circuits are required to ensure that the local oscillator is locked in phase to the incoming signal.

Let us assume that the incoming signal (in the absence of noise and through the ideal channel) is represented by $A_c m(t) \cos(2\pi f_c t + \varphi_c)$. Suppose we demodulate the received signal by first multiplying $r(t)$ by a locally generated sinusoid $\cos(2\pi f_c t + \varphi)$, where φ is the phase of the sinusoid, and then passing the product signal through an ideal LPF with bandwidth W . This process yields $\frac{1}{2} A_c m(t) \cos(\varphi_c - \varphi)$. So, depending on the value of φ , the detected signal is deviated or vanished. Therefore, we need a *phase-coherent* or *synchronous demodulator*. This phase-locked sinusoid to the phase of the received carrier at the receiver can be generated in two ways: by adding a carrier component to the transmitted signal (pilot tone) or using the phase-locked loop demodulator noted above and shown in Figure 9. The addition of a pilot tone has the disadvantage of wasting some portion of energy on the pilot. The PLL, on the other hand, generates a phase-coherent carrier signal that is mixed with the received signal in a single balanced modulator. The output of this modulator is then passed through a LPF of bandwidth W to keep the desired signal and eliminate “other terms.” See Proakis and Salehi (2002) and Lindsey and Simon (1978) for more information on the PLL’s characteristics and operation.

Figure 9: Demodulator for DSB-SC AM signal

Single-Sideband Amplitude Modulation

The reason to suppress the carrier component in the DSB-SC AM is that it contains no information. It can also be observed that the signal information transmitted in the LSB is the same as is transmitted in the USB. If either one is suppressed, it is possible to send the same information with half of the employed bandwidth $2W$ for two proposed techniques in which W is the bandwidth of the baseband information-bearing signal. This is the main motivation to introduce *single-sideband amplitude modulation* (SSB AM).

The SSB AM signal is represented as follows:

$$s(t) = A_c m(t) \cos 2\pi f_c t \mp A_c \hat{m}(t) \sin 2\pi f_c t \quad (10)$$

where $\hat{m}(t)$ is the *Hilbert transform* of $m(t)$, and plus or minus tells us which sideband we obtain. The Hilbert transform is basically a linear filter with $h(t), 1/\pi t \xrightarrow{\mathcal{F}} H(f) = -j \operatorname{sgn}(f)$, where $\operatorname{sgn}(\cdot)$ denotes the sign function. In fact, using the Hilbert transform is only one method to generate an SSB AM signal. Another method is to generate a DSB-SC AM signal and then employ a filter that is able to select either the USB or the LSB of the original signal.

As explained above, an *upper single-sideband* (USSB) AM can be obtained by eliminating the lower sidebands of a DSB-SC AM signal by passing $m(t)$ through a high-pass filter (HPF) with transfer function $H_U(f) = U(f - f_c) + U(-f - f_c)$, where $U(\cdot)$ denotes the unit step function. Therefore, the spectrum of the USSB AM signal $s_U(t)$ is given by

$$S_U(f) = A_c M(f - f_c)U(f + f_c) + A_c M(f + f_c)U(-f - f_c) \quad (11a)$$

where $M(f)$ represents the Fourier spectrum of $m(t)$. Similarly, a *lower single-sideband* (LSSB) AM can be obtained by eliminating the upper sidebands of a DSB-SC AM signal by passing $m(t)$ through a HPF with transfer function $H_L(f) = 1 - U(f - f_c) - U(-f - f_c)$, which is in effect the complement of the $H_U(f)$ in the frequency domain. Therefore, the spectrum of the LSSB AM signal $s_L(t)$ is given by

$$S_L(f) = A_c M(f - f_c)U(f + f_c) + A_c M(f + f_c)U(-f + f_c) \quad (11b)$$

Figure 10 shows the spectrum of two kinds of SSB AM for the message signal $m(t) \xrightarrow{\mathcal{F}} M(f)$ shown in Figure 4c, where $M(f)$ represents the Fourier spectrum of $m(t)$ and $M(0) = M(f)|_{f=0}$. In Figure 10, the USSB AM spectrum is shown in white while the LSSB AM spectrum is gray. We observe that the bandwidth occupancy of this signal is W (Haykin 2001; Gagliardi 1988; Couch 2001).

Figure 10: SSB AM spectra

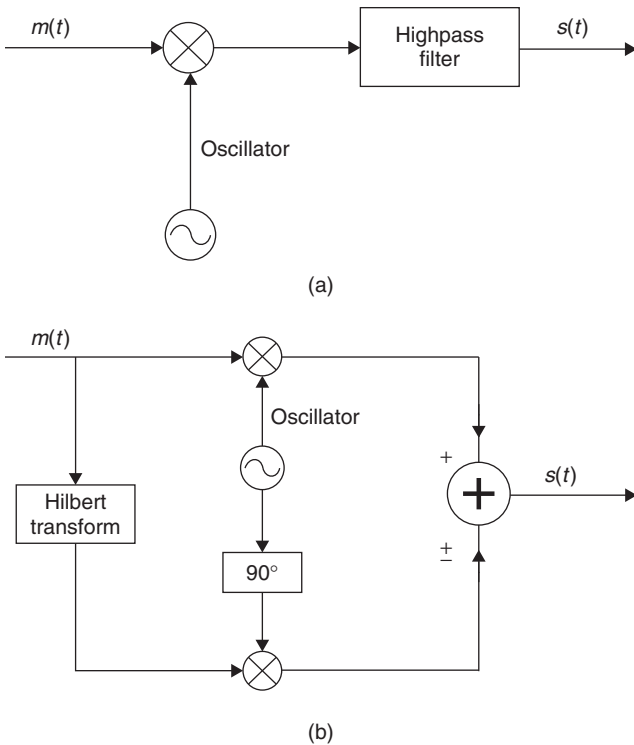

Figure 11: Generation of SSB AM signal: (a) Selective-filtering method, (b) Phase-shift method

Generation of SSB AM signals

Two methods are commonly used to generate SSB AM signals. The first uses sharp cutoff filters to eliminate the undesired sideband; the second method uses phase-shifting networks based on the Hilbert transform. These methods are shown in Figure 11 (Proakis and Salehi 2002; Lathi 1998).

Selective-Filtering Method. We can produce an SSB AM signal from DSB-SC AM by filtering off one of the sidebands as shown in Figure 11a. The filtering process is relatively difficult to accomplish at high frequency when the sideband separation would be a tiny fraction of the filter center frequency. The problem is considerably eased if the initial modulation takes place at a low carrier frequency (in the range of 100 kHz). The selected sideband can then be shifted to the required frequency range—from 3 to 30 megahertz (MHz)—by a second modulation. As the

Figure 12: Demodulator for SSB AM signal

sidebands of the second modulation are spaced with a wider distance in frequency, less exact filtering is necessary.

Phase-Shift Method. An interesting alternative method is based on the Hilbert transformation. Using two blocks of DSB-SC AM modulator, this modulator basically implements equation 10 for two different possible SSB AM signals (depicted in Figure 11b). Note that the two kinds of SSB AM signals are shown by \pm signs in equation 10 and correspondingly by \pm signs in Figure 11b.

Demodulation of SSB AM Signals

Because no carrier is transmitted in SSB AM, the demodulation of a SSB AM signal also requires coherent detection and local oscillators. In the case of signals with almost no DC power (such as speech signals), it is common to add a small carrier component to the transmitted signal. In such a case, a configuration similar to that in Figure 12 may be used to demodulate the SSB AM signal (Proakis and Salehi 2002).

Vestigial Sideband Amplitude Modulation

Vestigial sideband amplitude modulation (VSB AM) is usually used for wideband modulating signals such as television, where the bandwidth of the modulating signal can be extended as much as 5.5 MHz (with a total bandwidth of 11 MHz for a DSB AM transmission). With such a wide bandwidth, the cost of an SSB AM transmitter will be high because of frequency response requirements on the sideband filter, while the bandwidth requirement for DSB AM is not easily affordable. Therefore as a compromise, we allow a part of the unwanted sideband, referred to as a *vestige*, and the whole of the other side band to appear at the output of the modulator. This way, we simplify the design of the sideband filter at the cost of a little increase in the transmitted bandwidth. The resulting signal is called *vestigial sideband* (VSB) AM signal.

To generate the VSB AM signal, we generate a DSB-SC AM signal and pass it through a sideband filter with more relaxed characteristics compared to sideband filters used for SSB AM generation. If $h(t)$ and $H(f)$ represent the impulse and frequency responses of the employed sideband filter, respectively—that is, $h(t) \xleftrightarrow{\mathcal{F}} H(f)$ —then the modulated signal in both time and frequency domains is given by

$$s(t) = [A_c m(t) \cos 2\pi f_c t] \otimes h(t) \quad (12a)$$

$$S(f) = \frac{A_c}{2} [M(f - f_c) + M(f + f_c)]H(f) \quad (12b)$$

Based on the structure of the VSB AM demodulator (shown later in Figure 15), the filter $H(f)$ is chosen in a way that the message signal at the output of the demodulator is undistorted. In fact, the signal spectrum at the output of the ideal low-pass filter is $A_c/4 M(f) [H(f - f_c) + H(f + f_c)]$. Therefore, the VSB filter characteristics must satisfy the condition (Proakis and Salehi 2002; Lathi 1998):

$$H(f - f_c) + H(f + f_c) = \text{constant}, \quad |f| \leq W \quad (13)$$

Figure 13 shows the frequency response characteristics of a desired filter, $H(f)$, to generate the VSB AM signal in the case of the upper sideband VSB AM, as well as the frequency response of the upper VSB AM signal for the signal proposed in Figure 4c. As we observe, the bandwidth of $H(f)$ and therefore the bandwidth of VSB AM signal is $W + V$; an extra V is added to implement the VSB AM and relax the stringent condition on the ideal filters used in DSB AM. Similarly, the lower VSB AM signal is explained by considering the fact that the frequency response of lower VSB is the mirror of what is seen in this figure around the lines $\pm f_c$ (Proakis and Salehi 2002; Lathi 1998).

Generation of VSB AM signals

VSB AM is produced by filtering the corresponding DSB AM signal as discussed above. Figure 14 shows the general structure of a VSB AM modulator.

Demodulation of VSB AM signals

Figure 15 shows the general structure of a VSB AM demodulator. To implement this coherent detector, in VSB

Figure 13: Frequency response of the upper VSB AM signal and its corresponding filter, $H(f)$

Figure 14: Generation of VSB AM signal

Figure 15: Demodulation of VSB AM signal

a carrier is generally transmitted along with the message sidebands. The existence of the carrier component makes it possible to extract a phase-coherent reference for demodulation in a balanced modulator as shown in Figure 12 (Proakis and Salehi 2002).

ANGLE MODULATION

As an alternative to amplitude modulation, information can be transmitted by varying the phase angle of a sinusoidal signal. This variation can impact either the phase or the frequency of the sinusoid, which results in *phase modulation* (PM) or *frequency modulation* (FM), respectively. These two modulations are often jointly referred to as *angle modulation*. Angle modulation is inherently nonlinear, difficult to implement, and even more difficult to analyze. In addition, angle modulation has a bandwidth expansion property. The effective bandwidth in an angle-modulated signal is generally many times the bandwidth of the message signal. But angle-modulation systems have a high degree of noise immunity when the transmitted signal energy is quite limited (Haykin 2001; Roberts 1977).

Representation of FM and PM Signals

An angle-modulated signal is written as

$$s(t) = A_c \cos(\theta(t)) = A_c \cos(2\pi f_c t + \varphi(t)) \quad (14)$$

where $\theta(t)$ is the phase angle that is proportional to a function of the modulating signal, and $\varphi(t)$ is the phase drift. If we define its instantaneous frequency as $f_i(t) \triangleq \frac{1}{2\pi} \frac{d}{dt} \theta(t)$,

we get

$$f_i(t) = f_c + \frac{1}{2\pi} \frac{d}{dt} \phi(t) \quad (15)$$

This equation is the main one to define FM and PM. In fact, if $m(t)$ is the message signal, then FM and PM modulated signals are defined as follows:

$$f_i(t) - f_c = k_f m(t) = \frac{1}{2\pi} \frac{d}{dt} \phi(t) \quad \text{FM} \quad (16a)$$

$$\phi(t) = k_p m(t) \quad \text{PM} \quad (16b)$$

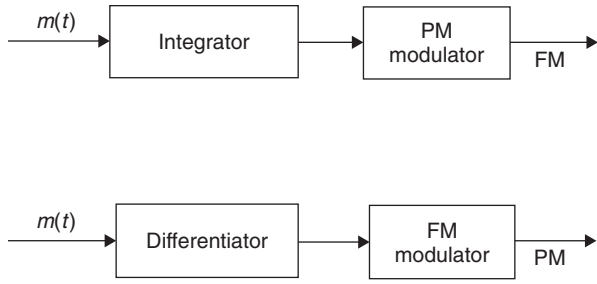

Figure 16: A comparison between FM and PM modulators

where k_f and k_p are frequency and phase *deviation constants*. This implies

$$\phi(t) = \begin{cases} 2\pi k_f \int_{-\infty}^t m(\xi) d\xi & \text{FM} \\ k_p m(t) & \text{PM} \end{cases} \quad (17)$$

This equation shows a close relationship between FM and PM signals: The phase modulation of the integral of a message is equivalent to its frequency modulation—or the frequency modulation of the derivative of a message is equivalent to its phase modulation. This duality characteristic, which is shown in Figure 16, helps us describe and analyze these two modulations in parallel.

Spectral Characteristics of Angle-Modulated Signals

Because of the inherent nonlinearities of angle-modulated signals that are caused by angle time variations, precise spectral analysis of these signals is extremely difficult. In fact, such an analysis usually results in mathematically intractable equations, even for simple message signals. In this part, we study the spectral characteristics of an angle-modulated signal for two simple cases: (1) a narrow-band angle-modulation system ($\phi(t) \ll 1$, for all t) and (2) a simple sinusoidal message signal. See Proakis and Salehi (2002) and Lathi (1998) for further readings on the (spectral) characterization of different message signals.

Narrowband Angle Modulation

If an angle-modulation system is designed such that $\phi(t) \ll 1$, for all t , then the phase-modulated signal is approximated by (Proakis and Salehi 2002)

$$S(t) \approx A_c \cos 2\pi f_c t - A_c \phi(t) \sin 2\pi f_c t \quad (18)$$

Therefore, the narrowband angle modulation is the same as amplitude modulation when the message signal $m(t)$ is modulated on a sine carrier rather than a cosine carrier. The spectrum analysis of this kind of angle modulation is similar to an AM signal; its bandwidth is twice that of the message signal's bandwidth. Of course, this bandwidth is just an approximation to the real bandwidth of the phase-modulated signal. For a precise characterization of the spectral properties of this signal, we should keep more

higher-order terms in the approximation of the modulated signal $s(t)$.

Angle Modulation for a Sinusoidal Signal

Considering a sinusoidal message signal $m(t) = A_m \cos 2\pi f_m t$, an angle-modulated signal (FM and PM signals) is represented by

$$s(t) = A_c \cos(2\pi f_c t + \beta \cos 2\pi f_m t) \quad (19)$$

where β is the modulation index—that is, $\beta_f \triangleq \frac{k_f A_m}{f_m}$

for FM modulation or $\beta_p \triangleq k_p A_m$ for PM modulation. It is also possible to extend the definition of the modulation index for a general nonsinusoidal signal, $m(t)$, as $\beta_f \triangleq \frac{k_f \max[|m(t)|]}{W}$ for FM modulation or $\beta_p \triangleq k_p \max[|m(t)|]$ for PM modulation, where W denotes the bandwidth of the message signal $m(t)$ (Proakis and Salehi 2002).

Because the modulating signal is a periodic function with period f_m^{-1} , we are able to rewrite it in terms of its Fourier series expansions. This expansion method for $m(t)$ results in another expansion for $s(t)$ based on *Bessel functions of the first kind of order n*—that is, $J_n(\beta)$ —as follows Proakis and Salehi (2002):

$$s(t) = \sum_{n=-\infty}^{+\infty} A_c J_n(\beta) \cos(2\pi(f_c + n f_m)t) \quad (20)$$

From this equation, we observe that in the case of a sinusoidal modulating signal, the actual bandwidth of the angle-modulated signal depends on $f_c \pm n f_m$ —that is, the bandwidth is infinite. However, because the Bessel function is accurately approximated by $J_n(\beta) \approx \frac{\beta^n}{2^n n!}$ for

small values of β , the amplitude of higher-order Bessels in this expansion rapidly tend to decrease. Therefore, we are able to define an effective bandwidth for this modulated signal. Usually, the effective bandwidth of an angle-modulated signal contains at least 98 percent of the signal power. Such a definition results in the effective bandwidth as

$$B_c \approx 2(\beta + 1)f_m \quad (21)$$

where β is the modulation index and f_m is the frequency of the sinusoidal message signal (Proakis and Salehi 2002). Substituting the appropriate values for β in FM or PM cases, the effective bandwidth B_c is given by

$$B_c = \begin{cases} 2(k_f A_m + f_m) & \text{FM} \\ 2(k_p A_m + 1)f_m & \text{PM} \end{cases} \quad (22)$$

We observe that the variations of A_m have almost the same effect on the variations of B_c in both FM and PM cases. However, in most cases of interest with a large value of β , the variations of f_m have a substantial effect on the variations of B_c of a PM signal compared to an FM signal (Shanmugan 1979; Roberts 1977).

Features of Angle Modulation

As a general fact, any modulation process involves the generation of new frequencies that are not present in the input signal. This is true for both amplitude- and angle-modulation schemes. Usually, amplitude-modulation methods are called *linear modulation methods*, although DSB AM is not linear in the strict sense. Specifically, angle-modulation methods are time-varying and nonlinear systems. Based on this nonlinearity, they have the feature of exchanging signal power for transmission bandwidth. This is a unique feature of angle-modulation schemes compared to amplitude-modulation methods. In fact, we can show that for an angle-modulation system, the SNR is roughly proportional to the square of the transmission bandwidth B_c (Lathi 1998; Roberts 1977).

Immunity of Angle Modulation to Nonlinearities (and Noise)

An interesting feature of angle modulation is its constant amplitude, which makes it less sensitive to nonlinearities. The effect of nonlinearities are lumped into the generation of some higher-order harmonics in the output of the nonlinear distortive component. These harmonics are easily filtered out by an LPF detector. Therefore, the nonlinearity does not destroy the information. Preserving the information in the presence of nonlinearity is the advantage of using this kind of modulation in microwave applications.

Generation of Angle-Modulation Signal

Basically, there are two ways to generate FM (angle modulation) signals: *indirect generation* from a narrowband angle-modulated signal or *direct generation* by variations of the frequency of a voltage-controlled oscillator.

Direct Generation

One method to generate an angle-modulated signal is to design an oscillator whose frequency changes with the input signal, biased at f_0 —that is, when the input voltage is zero, the oscillator generates a sinusoid with frequency f_0 . There are two approaches to design such an oscillator, which is usually called a *voltage-controlled oscillator* (VCO). One approach is to use a *varactor diode*, while the second approach is through a *reactance tube*. See Proakis and Salehi (2002) and Lathi (1998) for more details on these two approaches.

Indirect Generation

Another method to generate an angle-modulated signal is to first generate a narrowband angle-modulated signal and then change it to a wideband signal. These two steps are shown in parts a and b of Figure 17, respectively. As it is explained in the preceding section on the spectral characteristics of angle-modulated signals, the narrowband angle modulator is basically a conventional AM modulator with slight modifications.

The next step is to generate the wideband angle-modulated signal employing the narrowband angle-modulated signal. This is possible by applying the

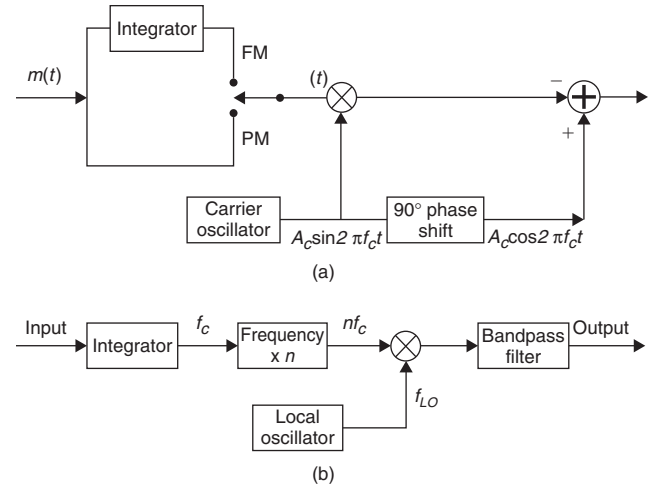

Figure 17: Indirect generation of analog modulated signal; (a) generation of narrowband angle-modulated signal; (b) generation of angle-modulated signal

signal at frequency f_c to a nonlinear element and then passing its output through a BPF at the central frequency, nf_c . If the frequency nf_c is not the desired carrier frequency, then we tune the frequency of the output signal using the local oscillator with frequency f_{LO} . This stage basically consists of a mixer and a BPF, and performs up or down conversion to shift the frequency to the desired center frequency. Therefore, using the narrowband modulated signal $A_c \cos(2\pi f_c t + \varphi(t))$, we have $A_c \cos(2\pi(nf_c - f_{LO})t + n\varphi(t))$ as the wideband angle-modulated signal (Proakis and Salehi 2002; Roberts 1977).

Demodulation of an Angle-Modulation Signal

The primary function of an angle-modulation detector is to produce an output that is proportional to the angle of the modulated wave—that is, the FM demodulator should produce an output proportional to the instantaneous frequency of the modulated signal, while the PM demodulator produces an output proportional to the phase of the modulated signal (see equation 16). On the other hand, as the structure of FM and PM modulators are almost the same (see Figure 17), here we just explain different methods to implement an FM demodulator.

The information in an FM signal is in the instantaneous frequency $f_i = f_c + k_f m(t)$. Therefore, a frequency demodulator should somehow be able to extract this information from the received modulated signal (with noise!). In general, there are two types of FM (angle) demodulators: a demodulator based on an AM demodulator and an *FM demodulator with feedback* (FMFB) (Haykin 2001; Proakis and Salehi 2002; Lindsey and Simon 1978; Roberts 1977).

FM Demodulator Based on AM Demodulator

We can implement an FM demodulator by an AM signal whose amplitude is proportional to the instantaneous frequency of the FM signal and then using an AM demodulator to recover the message signal. Figure 18 shows

Figure 18: A general FM demodulator

the general structure of this kind of FM demodulator in two steps.

To implement the first step in converting the FM signal to an AM signal, it is enough to pass the FM signal through a filter whose frequency response is approximately a straight line in the bandwidth of the FM signal; that is,

$$|H(f)| = a + b(f - f_c) \quad \text{for } |f - f_c| < B_c/2 \quad (23)$$

Many circuits can be used to implement such a filter. One candidate is a simple differentiator with $|H(f)| = 2\pi f$, while the other candidate is a balanced discriminator (Proakis and Salehi 2002). The whole purpose of this filter is to have a linear-shaped response at the output so as to have the instantaneous frequency of the modulated signal appear at the amplitude of the converted (AM) signal.

FM Demodulator with Feedback

Figure 19 shows a totally different approach to demodulate an FM signal by using feedback in the FM demodulator to narrow the bandwidth of the FM detector. In fact, the bandwidth of the discriminator and the subsequent LPF is designed to match the bandwidth of the message signal, $m(t)$.

An alternative to the FMFB demodulator is the use of a *phase-locked loop* (PLL). Figure 20a shows the general structure of a PLL-FM demodulator; its equivalent linearized structure in the presence of small phase error is depicted in Figure 20b. In this structure, the demodulator input is the modulated signal (phase), and the demodulator output is proportional to the message signal, $m(t)$. We assume that the input of the VCO is $v(t)$ —that is, the instantaneous output frequency of the VCO is $f_c + k_v v(t)$ where k_v ($k_v > 0$) is the VCO constant. Therefore, the output of the VCO is given by

$$y_v(t) = A_v \sin(2\pi f_c t + \phi_v(t)) \quad (24a)$$

$$\phi_v(t) = 2\pi k_v \int_0^t v(\xi) d\xi \quad (24b)$$

The phase comparator output is the phase error $\phi_e(t) \triangleq \phi(t) - \phi_v(t)$. In the case of a small phase error—that is, $|\phi_e(t)| \ll 1$ —we are able to use the linearized PLL structure depicted in Figure 20b. Using this equivalent

Figure 19: General structure of an FMFB demodulator

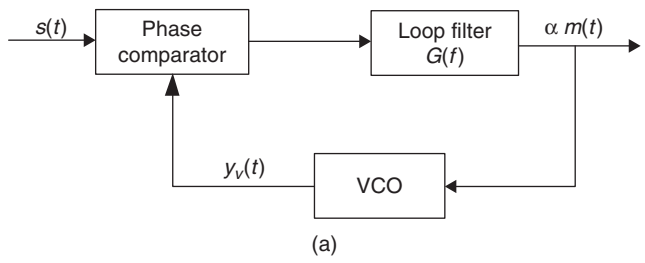

Figure 20: PLL-FM demodulator; (a) general structure, (b) linearized PLL

linear structure, we analyze the output of the PLL-FM demodulator (or the input of the VCO, $v(t)$). Based on this analysis (see Proakis and Salehi 2002), the output of the demodulator is proportional to the message signal—that is, $v(t) \propto m(t)$, if

$$k_v \left| \frac{G(f)}{f} \right| \gg 1 \quad (25)$$

Employing this condition, we get $v(t) \approx \frac{k_f}{k_v} m(t)$. Note

that the bandwidth of the filter $G(f)$ should be the same as the bandwidth of the message signal, W . This fact has the advantage of limiting the output noise to the bandwidth W . For some more references, see Haykin (2001), Ziemer and Tranter (2001), Freeman (1998), and Gitlin, Hayes, and Weinstein (1992) and references therein.

ANALOG MODULATION FOR DIGITAL SIGNALS

What we have studied to this point deals with analog transmission of the analog message signal, $m(t)$. In contrast, there are situations when the information-bearing signal is a digital signal that is a sequence of symbols that are selected from a fixed and finite number of possible symbols. In general, the analog modulation of digital signals is known as *passband digital transmission* as the spectrum of the signal is transformed to the passband frequency. Figure 21 shows different techniques used in this form of transmission: amplitude shift keying, frequency shift keying, and phase shift keying. Here we briefly explain these transmission schemes. See Chapter 7 for more details on passband digital transmission (Haykin 2001; Turin 1969; Smith 1985; Sklar 1988).

Figure 21: Analog modulation of digital signals or passband digital transmission; amplitude shift keying (ASK), phase shift keying (PSK), and frequency shift keying (FSK)

Amplitude Shift Keying

Amplitude shift keying (ASK) is the name used for AM when we use it to transmit data signals. The ASK signal is generated by multiplication of data signals by a carrier $A_c \cos 2\pi f_c t$. This process effectively shifts the data spectrum to the carrier's center frequency. As seen for DSB AM, the bandwidth of ASK is twice that of the original data signal because it contains the carrier plus upper and lower sidebands. This means that the original 110-baud signaling rate requires a transmission bandwidth of 220 hz using ASK.

Frequency Shift Keying

Frequency shift keying (FSK) is the binary equivalent of FM. In this case, a binary 0 is transmitted as a carrier at frequency f_1 , and a binary 1 is transmitted as a tone, f_2 . In this way, the binary signal effectively modulates the frequency of the carrier. Although, strictly speaking, FSK is the same as FM, it is usually more convenient to consider FSK as the sum of two ASK waveforms with different carrier frequencies. The spectrum of the FSK is thus the sum of the spectra of the two ASK waves. Therefore, the bandwidth of the FSK signal is given by $B_c \approx 2W(\beta + 1)$, where W is the bandwidth of the data signal and β is the modulation index (Smith 1985; Sklar 1988). This equation is similar to the corresponding rule for continuous FM, as proposed in equation 21. This rule is usually known as *Carson's rule*.

Phase Shift Keying

Phase shift keying (PSK) is the binary equivalent of PM. In PSK, the binary information-bearing signal is transmitted either as zero phase shift or a phase shift of π radians. This is equivalent to multiplying the carrier signal by either $+1$ or -1 , respectively. The bandwidth is thus the same for ASK. Because there is no DC component in the modulating signal, the carrier in the PSK spectrum is suppressed. This form of PSK is sometimes referred to as binary PSK (BPSK), which is equivalent to binary DSB-SC AM.

CONCLUSION

In this chapter, we studied the essentials of analog transmission of message data in the form of continuous-wave information-bearing signals. The chapter covers important techniques of generating and demodulating continuous-wave modulated signals. This analog form of modulation is made up of a sinusoidal carrier that encodes the message data in its amplitude or angle (frequency or phase) to form the information-bearing signal. Therefore, we distinguished two categories of analog transmission—amplitude modulation and angle modulation—and discussed different forms of each category.

Amplitude modulation (AM) is classified into four types: (1) double-sideband AM, in which the upper and lower sidebands are transmitted in full, accompanied by the carrier wave; (2) double-sideband suppressed carrier AM, in which only the upper and lower sidebands are transmitted; (3) single-sideband AM, in which only the upper sideband or lower sideband is transmitted; and (4) vestigial sideband AM, in which almost the whole of one sideband and a vestige of the other sideband are transmitted in a complementary manner.

Angle modulation is classified into frequency modulation (FM) and phase modulation (PM). In FM, the instantaneous frequency of a sinusoidal carrier is varied in proportion to the message signal; however, in PM, the phase of the carrier is varied in proportion to the message signal.

GLOSSARY

Additive white Gaussian noise (AWGN): A communication channel in which the only impairment is the linear addition of wideband or white noise with a constant spectral density and a Gaussian distribution of amplitude.

Amplitude modulation (AM): A technique used in electronic communication, most commonly for transmitting information via a radio carrier wave, and works by varying the strength of the transmitted signal in relation to the information being sent.

Amplitude shift keying (ASK): A form of modulation that represents digital data as variations in the amplitude of a carrier wave.

Bandpass filter (BPF): A device that passes frequencies within a certain range and rejects (attenuates) frequencies outside that range.

Double-sideband (DSB): A technique in conventional AM transmission in which the carrier and both sidebands are present.

Double-sideband suppressed carrier (DSB-SC): A form of DSB in which the carrier is removed.

Frequency modulation (FM): A form of modulation that represents information as variations in the instantaneous frequency of a carrier wave.

Frequency shift keying (FSK): A form of frequency modulation in which the modulating signal shifts the output frequency between predetermined values.

Lower sideband (LSB): A band of frequencies lower than the carrier frequency.

Lower single-sideband (LSSB): A technique in AM transmission in which the lower sideband is present.

Low-pass filter (LPF): A filter that passes low frequencies but attenuates (or reduces) frequencies higher than the cutoff frequency.

Phase-locked loop (PLL): A closed-loop feedback control system that generates and outputs a signal in relation to the frequency and phase of an input “reference” signal.

Phase modulation (PM): A form of modulation that represents information as variations in the instantaneous phase of a carrier wave.

Phase shift keying (PSK): A digital modulation scheme that conveys data by modulating the phase of the carrier wave.

Pulse-amplitude modulation (PAM): A pulse modulation technique for a signal in which the message information is encoded in the amplitude of a series of signal pulses.

Pulse-duration modulation (PDM): A pulse modulation technique for a signal in which the message information is encoded in the duty cycle of a series of signal pulses.

Pulse-position modulation (PPM): A pulse modulation technique for a signal in which the message information is encoded in the position of a series of signal pulses.

Signal-to-noise ratio (SNR): An electrical engineering concept defined as the ratio of a signal power to the noise power corrupting the signal.

Single-sideband (SSB): A technique in AM transmission in which one of the sidebands (either lower or upper) is present.

Upper sideband (USB): A band of frequencies higher than the carrier frequency.

Upper single-sideband (USSB): A technique in AM transmission in which the upper sideband is present.

Vestigial sideband (VSB): A sideband that has been only partly cut off or suppressed.

Voltage-controlled oscillator (VCO): An electronic oscillator specifically designed to be controlled in oscillation frequency by a voltage input. The frequency of oscillation is varied with an applied DC voltage, while modulating signals may be fed into the VCO to generate FM, PM, or PDM.

INTRODUCTION

The pervasive use of voice communications systems in society cannot be overemphasized. Today, a *key telephone system* (KTS) enables its users to make telephone calls by simply pushing buttons (hence, the name *key*). Telephone systems have become highly sophisticated with multiline telephones and accessories that allow a user to place a call on a selected line while simultaneously placing another caller on hold and using intercom features to communicate between phones at the same location—or even activating other systems and devices. Understanding how the basics of that technology work and how they can be made to serve individual and corporate users is vital.

The digital communications revolution has resulted in the convergence of voice, data, and video communications. With communications technology advancements, new services and their associated costs must be considered in light of the business or social functions they are supposed to serve. This chapter is intended for those who have an interest in the topic, without assuming they already have extensive knowledge of the subject. It presents the development and applications of voice communications technologies, starting with the basics (such as how the voice is translated into electric signals) to more advanced and contemporary topics (such as VoIP).

A BRIEF HISTORY OF VOICE COMMUNICATIONS

Modern voice communications have been historically dependent on the invention of the telephone and the evolution of its technology. However, when the telephone was

first invented, it did not necessarily receive the welcome it deserved. At the time, it was considered by the telegraph industry as having too many shortcomings to be seriously considered as a means of communication and thus inherently of no value. Over the years since, however, voice communication technologies advanced and their use became global.

In 1885, the American Telephone and Telegraph (AT&T) Company was incorporated as a subsidiary of the American Bell Telephone Company. AT&T's corporate charter laid out the firm's mission:

Connect one or more points in each and every city, town or place in the State of New York with one or more points in every other city, town or place in said State and in each and every other of the United States, Canada and Mexico; and each and every of said cities, towns and places is to be connected with each and every other city, town or place in said states and countries, and also by cable and other appropriate means with the rest of the known world (AT&T 2007).

Such a bold statement was made less than a decade after the telephone's invention. In reality, it took AT&T several decades to accomplish that mission.

Some of the major milestones in its history in the United States are shown in Table 1.

THE TELEPHONE SYSTEM Transmitter and Receiver Operation

The first task in technology-based voice communications is to translate the voice's acoustic waves into electronic

Table 1: Major Events in U.S. Telecommunications History

Year	Event
1837	Invention of the telegraph by Samuel Morse
1876	Invention of the telephone by Alexander Graham Bell
1934	Creation of the Federal Communications Commission (FCC) to regulate interstate telephone traffic
1958	First U.S. communications satellite sent into orbit
1959	FCC approves private microwave communications networks
1963	First geosynchronous orbiting satellite (SYNCOM II) launched
1984	Divestiture of American Telephone and Telegraph (AT&T)
1985	Cellular radio telephones introduced
1996	Telecommunications Reform Act of 1996 passed

signals. These signals are then able to travel over wired and wireless networks. Upon reaching their destination, they are retranslated back into their original sound form for the receptor to understand. These translation and re-translation tasks are handled at the telephone's mouth-and earpieces, respectively.

Voice waves spoken at the mouthpiece push against a sensitive flexible diaphragm that in turns presses together carbon granules that connect two electrodes (see Figure 1). The degree of conductivity of the granules and consequently the strength of the signal passing between the electrodes depends on how well the granules are compressed together. Hence, the variation in the sound waves at the mouthpiece vibrates the diaphragm, which changes the degree of compressions of the granules, resulting in signals with variable strengths passing the two electrodes and emulating the variations in the original sound waves.

At the receiving end, the earpiece contains an electromagnet that faces a moveable diaphragm. Arriving electric signals create variable levels of magnetism in the electromagnet, which in turn causes the diaphragm to move in a corresponding way. This produces sounds that correspond to the original sound waves entered into the mouthpiece.

Dialing Systems

The telephone numbering system was created in order to identify each user in a unique way. Today's telephone number systems include a comprehensive list of country codes for individual nations and city codes, in addition to individual telephone numbers. In any given country, some form of hierarchical system is followed in assigning the telephone numbers.

For example, in the United States, the first three digits signify the area code, which is associated with a particular geographic location. This is followed by a prefix of three digits that signify the local switching office or exchange, and then four digits that identify the individual subscriber. Originally, all area codes in the United States had a 1 or a 0 in the middle digit while no exchange numbers were allowed to have those numerals, which made it easier for telephone switches to differentiate between the two. Once all of the areas codes that followed that system were completely used, new area codes with numerals other than a 1 or a 0 as the center digit were introduced, starting with area code 770, which is used outside of Atlanta, Georgia (Goldman and Rawles 2004, 170).

Rotary Dialing

The earlier form (and one still used in some countries) of dialing phone numbers was done though a rotating disc on the face of the telephone set that carried the numerals 0 through 9. By manually rotating the disk using one of those ten digits, the telephone produces a string of electric pulses that correspond to the dialed digit. Once those electrical pulses reach the phone company's local exchange, the arms of electromechanical switches move to create the needed connection between the caller and the call destination. This system is slow, inaccurate, and no match for the incredible growth in demand for voice communications.

Dual Tone Multifrequency: The Touch Tone System

The clumsiness and frequent inaccuracy of that rotary system led to the development of a more user-friendly and accurate system known as *touch tone dialing* or *dual tone multifrequency* (DTMF). In DTMF, each digit in the phone number is "dialed" by simply pushing down a button to create a signal with a unique frequency that is associated in the telephone network with a particular digit (see Figure 2). As the signals arrive at the switching office, they are processed by electronic microprocessors that control smaller and faster relays that make the connections.

VOICE COMMUNICATIONS NETWORK INFRASTRUCTURE

The Central Office

Earlier generations of telephone networks required massive hardwiring of towns and cities in order to connect different callers directly to each other through dedicated wires. As both the number of telephone users and their

Figure 2: The touch tone dialing system. Source: Reprinted with permission from J. E. Goldman. 2004. *Applied data communication*. New York: John Wiley & Sons

desire to reach more people increased, hardwiring all of the necessary lines became a nightmare, and cities became blighted with jungles of wires hanging on telephone poles. The solution came with the introduction of the *switching office* (also known as *central office*, or CO). Because each individual user is connected to a particular CO, only one wire is needed per user. By interconnecting the switching offices, callers anywhere can reach each other with minimal wiring requirements because connections are established through the switching offices.

The CO method required having a telephone numbering system (as previously discussed) that was totally dependent on human operators—commonly known as *switchboard operators*—to physically plug cables into corresponding sockets to create the connections. First, young men were hired to do the job, but with many complaints about their lack of professionalism and prank calls, they were replaced with female operators who were better trained and more professional in conducting the tasks. The system worked well for awhile until an automated switchboard was developed. Strangely enough, the automated switchboard was apparently invented by Almon Brown Strowger, an undertaker in Kansas City, Missouri (Sveum 2000, 117). Strowger was convinced that he was losing customers to a competitor, whose wife was a switchboard operator and who intentionally routed business calls intended for Strowger to her husband's office.

Today, all over the world automated systems in switching offices facilitate connections in the voice communications industry. The switching office usually serves a limited geographic region and is connected to end users by a connection known as “the last mile” or the “local loop” (Figure 3). As mentioned before, a switching office is assigned a unique exchange number in the telephone system that end users inherit as the prefix of their telephone numbers.

Figure 3: The local loop

Public Switching Telephone Network

The *public switching telephone network* (PSTN) is the oldest interconnected worldwide network that crosses many countries and telephone company boundaries. It is also known as the *plain old telephone service* (or *system*) (POTS). In many countries, the telephone company is government-owned and typically considered part of what is commonly known as a *public* (or *post*), *telephone* and *telegraph* (PTT); in these cases, it enjoys complete monopoly over a nationwide market, which is similar to what AT&T had before its divestiture in 1984.

A telephone network is typically set up as a hierarchy of switching offices connected by *trunk lines*. The value of a hierarchical structure is in its efficient way of providing adequate switching capacity in the network without unnecessary investment. In the United States, AT&T built a hierarchy of five levels known as *classes*. A class 5 CO, placed at the bottom of the hierarchy, is the local switching office that is directly connected to end users. A call from one user to his or her immediate neighbor is most likely to be routed directly through the same class 5 CO, freeing the rest of network from the burden of having to carry that traffic.

A call placed to a destination that cannot be reached directly through the same exchange is moved up the hierarchy to a class 4 switching office that can then route

Figure 4: Routing calls through the PSTN hierarchy

the call down to the class 5 CO in the locality of the destination or move it up to a class 3 or higher CO until an open route to the destination is established. The call is then routed down until it reaches a class 5 CO and is then routed to the intended party (Figure 4).

Local Access and Transport Areas

The geographic region served by a telephone company can be divided into different areas known as *local access and transport areas* (LATAs). In the United States, AT&T divided the country into 161 LATAs (Goldman and Rawles 2004, 169). A call bound to a destination within a given LATA is considered a *local call* for the telephone company, and the customer is charged accordingly (Gelber 1997, 130). A call placed to a number outside a designated LATA is considered either an *out-of-area call* or a *long-distance call*, depending on the destination. *Intra-LATA* calls are typically handled by a local phone company, which is usually referred to as a *local exchange carrier* (LEC); *inter-LATA* calls are handed over to an *interexchange carrier* (IXC) for delivery to the LATA of the called

party (see Figure 5). Note that a geographic region covered by an area code is not necessarily considered a LATA. In fact, several LATAs could be covered by a given area code (Goldman and Rawles 2004, 164).

Point of Presence

For an IXC to access an end user, it can set up its own network, in essence duplicating the LEC's network. A more cost-efficient way is to simply rely on the LEC network that already exists to provide access to the "last mile" by connecting its network directly to one of the switching offices of the LEC. The switching office where the IXC connection to the LEC network takes place is known as *point of presence* (POP).

An IXC that can provide service to international calls is known as an *international common carrier* (ICC). Countries negotiate not only which ICCs may provide service in their territories but also settlement call charges on bilateral basis. Such bilateral agreements often bring uneven pricing schemes for calls placed to neighboring countries.

Figure 5: Local area and transport areas and POPs

Trunk Lines

The switching offices placed in different service regions and neighborhoods are interconnected through high-speed lines that use different types of multiplexing technologies that allow carrying multiple conversations simultaneously and thus improve network efficiency. Those lines that interconnect the switching offices are known as *trunk lines*. Earlier generations of trunk lines were built to handle analog signals. Over the years, most have been upgraded to carry digital signals, and many have been upgraded to fiber-optic cabling, even though many of the so-called last mile connections continue to be analog lines.

VOICE DIGITIZATION TECHNOLOGIES

Digital signals provide better quality and capacity utilization compared to analog signals, leading the telecommunications industry to shift to digital technologies in their infrastructures, including in switching offices and trunk lines. Digital signaling technologies translate a message into an equivalent binary sequence of 0's and 1's. This not

only allows information to be coded more precisely (see PCM below) but also allows easier error detection and correction during transmission. Attempting to accomplish the same level of quality through analog transmission is more difficult, imprecise, and inefficient.

To allow an analog signal arriving from a local loop to be handled by a digital switching office and then digital trunk lines, a digitization process is employed to convert the analog signal into an equivalent digital signal. To represent analog signals, which have continuous form, into digital signals, which are discrete in nature, *voice digitization* is employed. Voice digitization relies on a sampling theorem that states that if a signal is sampled at regular intervals of time and at a rate higher than twice the significant signal frequency, then the samples will contain all of the original signal's information. Given that most human voice communications are typically between 300 hz and 3400 hz (a bandwidth less than 4000 hz), some 8000 samples per second are considered a sufficient and acceptable standard in voice digitization technologies, which include various forms of pulse modulation (see Figure 6).

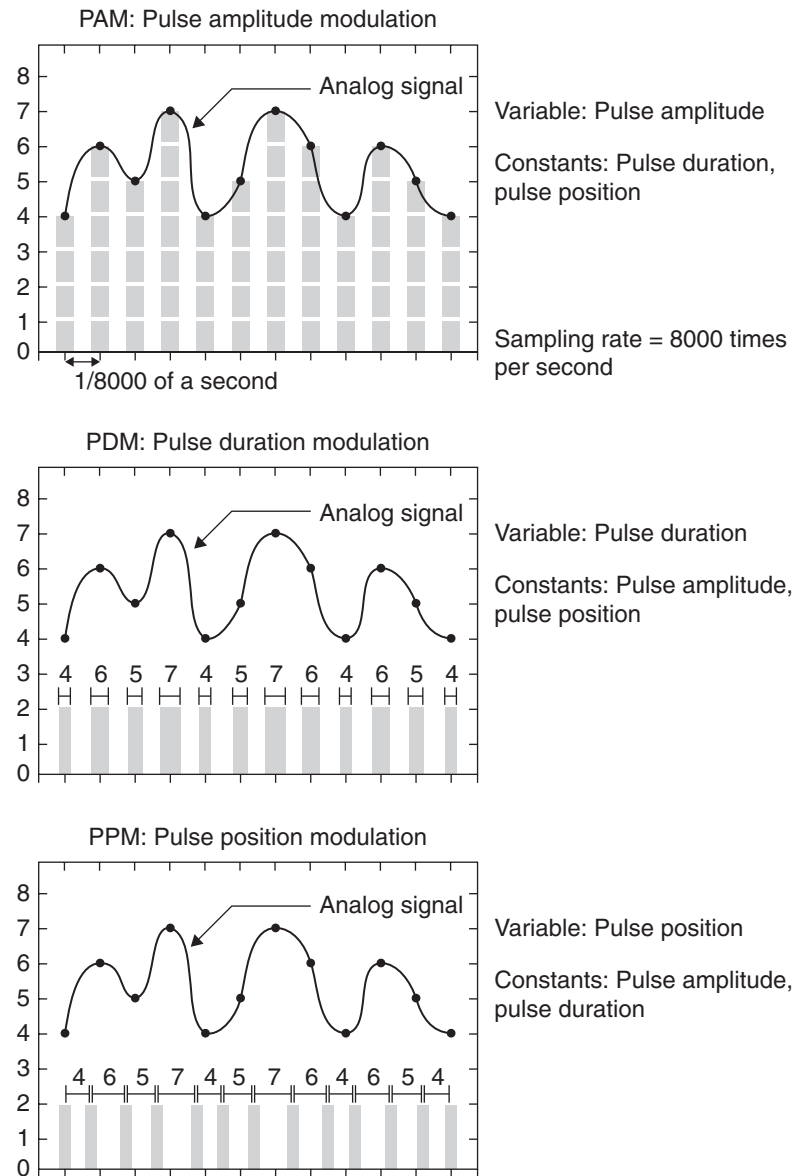

Figure 6: Voice digitization techniques system. Source: Reprinted with permission from J. E. Goldman. 2004. *Applied data communication*. New York: John Wiley & Sons

Pulse Modulations

Four main methods of pulse modulation are used in modern voice digitization: pulse amplitude modulation, pulse duration modulation, pulse position modulation, and pulse code modulation.

Pulse amplitude modulation (PAM) produces electrical pulses with variable *amplitude* (or *signal strength*) in ways that correspond to variations in the analog signal. *Pulse duration modulation* (PDM) produces electrical pulses with variable *durations of time*, also in ways that correspond to variations in analog signals. *Pulse position modulation* (PPM) produces electrical pulses with variable *durations between pulses* (Goldman and Rawles 2004, 174).

Pulse code modulation (PCM) is currently the most widely used form of digitization technology. PCM samples the analog signal (as stated earlier, at the rate of 8000 samples per second) and then produces binary codes that correspond to the variations in the analog signal (see Figure 7). A *coder-decoder* (codec) device or software is used to facilitate that process (Fitzgerald and Dennis 2005, 98).

Voice Compression

Voice compression is a sophisticated form of PCM known as *adaptive differential PCM* (ADPCM) that transmits only the approximate difference between two consecutive pulses, which is a more efficient way to use available bandwidth to send and receive communication signals. Voice compression is widely used in today's telephone systems.

VOICE COMMUNICATIONS SERVICES

Digital signals brought new flexibility to telephone networks and made possible the introduction of more advanced services. Among the voice communications services that are popular with many businesses are *toll-free services*, *900 services*, and *wide area telecommunications services* (WATS) (Beyda 2005, 19).

Toll-Free Service

Toll-free service is not as free as it sounds. It is only free to the caller because the called party (the toll-free service

Step 1: Sample Amplitude of Analog Signal

subscriber) pays for the calls. This way customers or other users can reach the toll-free service subscriber in a convenient and economic way, calling from anywhere, anytime, and for any length of time without having to worry about the costs of their calls. The toll-free service provider is typically one of the IXC's, which charges its subscribers a cheaper rate than that for direct dial services.

In the United States, for many years the 800 area code signified that the number was a toll free number. However, over the years, the demand for toll-free numbers grew along with the desire of many businesses to have numbers that could be easily associated with their names, products or services, or even their logos (such as 800-CALL ATT). This required the introduction of new area codes such as 866, 877, and 888. By having these area codes designated in the telephone network for toll-free service, the accounting task for these calls can be easily handled.

Another challenge that toll-free service providers faced was that their numbers were assigned as blocks to particular carriers. That meant that when a subscriber changed its carrier, it could no longer hold onto the same toll-free number that it had used and publicized on its literature or in its commercials. The solution came in the form providing access to the carriers' switching offices through a master toll-free numbers database. In this way, switching offices could automatically determine which carrier was supposed to carry particular toll-free traffic.

900 Services

Like toll-free services, a 900 service is an inbound call to the subscriber but paid for by the caller and usually at a much higher rate than a normal long-distance call. Good examples for subscribers to such services include technical support companies and tax consultation services. More recently, U.S. embassies in some countries provide a similar service for callers who want to check on the status of their visa applications (Forouzan 2003, 185).

Wide Area Telecommunications Services

With a *wide area telecommunications service* (WATS), a subscriber (typically a business) may buy calls in a specified volume at a highly discounted price from the telephone company. In this way the subscriber enjoys substantial savings when compared to paying for individual calls. The main advantages to the carrier are a guaranteed cash flow as well as better capacity planning for its network (Forouzan 2003, 185).

PRIVATE BRANCH EXCHANGE

A *private branch exchange* (PBX) is a privately owned, on-site switching telephone facility operated by an enterprise. It emulates the function of a CO in the PSTN. The PBX and all of its lines that are connected to individual employees are the property of the enterprise, so all internal calls are handled by the PBX without the involvement of the phone company. However, local and long-distance calls are routed from the PBX to the local phone company or an IXC respectively. In addition to providing

telephone-switching capabilities, a PBX supports many of the business needs that have come to be part of normal organizational activities such as conference calls, call waiting and call forwarding, voice messaging, and automatic call distribution as well as providing links to databases.

Purpose and Benefits

An enterprise that wishes to provide hundreds or thousands of workers with their own telephone service and unique phone numbers can get similar numbers of lines from a telephone company. This would have a tremendous cost, however. Because it is unlikely that all users will be on the phone at the same time, using a PBX would facilitate phone services by using only few lines from the local company and providing each user with an individual phone number. Internal calls can be made using *reduced dialing*—that is, by using the last four or five digits of the phone number—while external calls can typically be made by first dialing “9” to request an outside line from the PBX. Initially, a PBX would be found at a medium-to large-sized business enterprise, government agency, or educational institution, but PBXs now are available in much smaller sizes and at more affordable prices (Thurwachter 2000, 531).

Architecture

A PBX is made of four major components: the central processing unit, station or line card, trunk card, and a switching matrix (Goldman and Rawles 2004, 198).

The *central processing unit* (CPU) is the brain of the PBX and is responsible for controlling the switching matrix and managing the call traffic of the network as well as facilitating the services requested by a user such as call waiting, call forwarding, voice mail, and so on.

The *station* (or *line*) *card* is the point of contact between the individual user and the network. A PBX is usually built according to a modular design of station cards, providing the flexibility needed to expand the PBX's capacity as the number of users increase.

The *trunk card* connects the PBX to a telephone company for external local and long-distance calls.

The *switching matrix* is responsible for creating, maintaining, and terminating the needed physical connections between the callers. If the call is intended for an internal number, then an electronic connection is established through the matrix by connecting the station cards of the caller to the intended destination's card. For calls placed to outside numbers, the switching matrix routes the call to the trunk card, and from there to the local phone company or directly to the point of presence of an IXC (see Figure 8).

Features and Services

PBX provides four main categories of features:

1. users-related PBX services,
2. switchboard operator-related or receptionist-related services,

Figure 8: The PBX architecture system. Source: Reprinted with permission from J. E. Goldman. 2004. *Applied data communication*. New York: John Wiley & Sons

3. data and voice integration, and
- 4 control over the usage of PBX and organization's resources.

First, user services include commonly used features such as display of dialed number, speed dialing, redialing of the last number, call waiting and playing on-hold music or messages, call forwarding, automatic (incoming) number identification, conference calling, intercom, and camp on (Panko 2005, 526).

Most of these features are self-explanatory, but *camp on* may need clarification. This feature frees the user from the frustration of calling a number that is constantly busy. The user dials the desired phone number, pushes the "camp on" button, and hangs up. The system then automatically keeps dialing the number as many times as it has been programmed to do; once the call gets through, the phone on the caller's side rings to signify that the called party has been reached (Beyda 2005, 28).

Second, there are those PBX-supported tasks that were traditionally carried out by human receptionists, such as the following:

- Distributing incoming calls to appropriate destinations. This is handled by a feature called *automatic call distribution* (ACD), which answers incoming calls and then routes them to the intended person or department or the next available help desk.
- Taking messages for individuals who are away from their desks or on other lines. This is handled by an electronic voicemail feature.
- Paging someone who is away from his or her desk such as a plant manager or physician who is making his or her rounds.
- Automatic nighttime transfer of calls to a guard station or an answering service as in the case of an emergency call that arrives after working hours at a physician's office.

Third, PBX data and voice integration allows the system's users to use their phones as input/output devices (instead of a computer terminal) to access data stored in computer files. This feature is different from computer telephony integration, which will be discussed later, in that the telephone is the main input/output device. Among the most popular features of data and voice integration are

interactive voice response and interfacing with wide area networks (Fitzgerald and Dennis 2005, 449).

Interactive voice response (IVR), which is widely used in phone banking, allows callers to use the telephone to interface with a bank's database.

Interfacing with a *wide area network* (WAN) connection such as an *integrated services digital network* (ISDN) or a leased T1 lines allows the PBX to support voice and data traffic simultaneously in an organization.

Finally, a PBX can collect a wealth of data through its extensive call monitoring and control features. That enables an organization's management to monitor the use of resources, improve efficiency, and have better control over assets. Among those features are least cost routing, station message detail reporting, and call restriction.

In *least cost routing*, a PBX can automatically route outgoing calls in the least expensive way, given different options of long-distance carriers or WATS (described earlier).

Station message detail reporting (SMDR) monitors and reports all incoming and outgoing calls with detailed charges. With this feature, management can monitor how users spend their time on the phone (e.g., to see whether they are talking to family and friends or conducting legitimate business), how long it takes to answer customer questions or process orders, and how many sales calls are made by a particular salesperson on any given day. SMDR can provide a *nonrepudiation capability* that allows management to investigate a customer's complaints about important orders (placements, cancellations, and so on) and whether and when a call took place and who answered a particular call.

Call restriction is another important feature that prevents certain extensions from making external calls, long-distance calls, or 900 calls.

Common PBX standards allowed for the interoperability of PBX systems from different manufacturers, which made it possible for an organization to mix and match different components of its telephone system (central or desk units). The major vendors of PBX systems are Avaya, Nortel, Lucent Technologies, NEC, Mitel, and Siemens Rolm. Some newer PBX systems are built in scaled-down versions with limited features that are just enough to support the needs of a small or home office. Others are built with wireless integration capabilities that can support the increasing growth in wireless network infrastructures.

When selecting a PBX system, careful consideration is needed to ensure that the desired features are available or can be supported by the system, because certain features need to be available in the station (desk) unit and be supported by the system (central) unit. In general, station features include automatic redial, call forwarding, speed dialing, call transfer, call waiting, camp on, and conference calling. System features, on the other hand, typically include automatic call distribution, data communication, least cost routing, paging, SMDR, and voice messaging.

Centrex

A Centrex service could simply be defined as a PBX that is physically located at the central office of a local phone company (Stallings 2005, 23). With a centrex, an organization does not need to invest in a PBX with all of its related costs of operation, maintenance, and upgrades; instead, it leases switching capacities from the local phone company at the local CO. Members of an organization can still call each other with reduced dialing, using only the extension of the called party. Although those calls are physically routed through the phone company's CO, they would be considered internal to the organization and not charged by the phone company as local calls (Crane 1999, 680).

A centrex can be an economical alternative for an organization that cannot afford the up-front cost of buying a PBX but wants the flexibility of adding more switching capacity as the organization grows. On the one hand, a centrex frees an organization from the headaches related to capacity management, operation and maintenance costs, and keeping up with constant PBX technological advancements. On the other hand, the phone company enjoys a guaranteed business and cash flow in addition to leveraging its investment in CO switching capabilities that otherwise could have been idle.

Virtual PBX

A *virtual PBX* is created by interconnecting several PBXs at one site or at multiple sites, often by leased lines (see Figure 9). Users within the same organization across cities or even countries can access one another with reduced dialing and substantially cheaper cost than having to pay for hundreds of long and overseas calls.

Figure 9: The virtual PBX

An example of a virtual PBX is found at the University of Maryland, College Park, which uses two PBX units. One unit mainly serves student dorms; the other serves faculty, staff, and administration. Faculty and staff calls are mostly placed during normal daytime working hours while students are in their classes. Most of the students' calls are placed in the afternoon and later when most faculty and staff have left for the day. By tying together the two PBX units, the university is able to balance traffic load between the two PBXs by taking advantage of the idle capacity of the PBX that is not heavily in use at the time.

Note that a virtual PBX can be created by tying together a number of centrex facilities that can be configured by the centrex-hosting local phone company. Similarly, a global virtual PBX can be implemented for a multinational corporation through international common carriers (ICCs), which are telephone companies that provide international service (e.g., Sprint, British Telecom, and Deutsch Telecom).

Automatic Call Distribution versus PBX

Automatic call distribution (ACD), which was discussed earlier, can be part of as well as ancillary to a PBX. A business such as an airline's ticketing center may get ACD functionality from a stand-alone ACD system without having to invest in a full-fledged PBX system. Just as with the ACD featured in a PBX, incoming calls are answered, the caller or type of service requested is identified, and then the call is routed to the right extension to handle that call (Carr and Snyder 2003, 58).

Digital PBX

For many years, organizations had to invest in separate voice and data communications infrastructures, which were typically managed by two different departments. The voice network was managed by a facilities department, while the data network was managed by the information technology department. That distinction was meaningful when voice was coded and transmitted as analog signals while data was primarily transmitted in a digital form. However, the digital communications revolution converged different means of communications: voice, data, video, and images. Under pressure to cut the cost of duplicated resources and to minimize departmental conflicts, organizations realized that they had to unify their information (including voice and data) systems into completely digital networks. That need was fulfilled by the introduction of digital PBXs that were able to handle both voice and data networks simultaneously and route outgoing voice and data traffic to different voice and data networks (Carr and Snyder 2003, 59). Organizations now can deal with just one service provider to manage all of their investment in communications technologies. Users can plug their desktop computers into the telephone network and communicate without having to go through a modem. By avoiding having to convert signals back and forth between analog and digital led to major improvements in the network's quality, speed, and throughput.

Standards

The International Organization for Standardization (ISO) has developed standards for interoperability between PBXs that are made by different vendors. This has allowed enterprises the flexibility they need to shop around and mix and match equipment that best fits their needs without being chained to a single vendor. ISO's *Q-signaling* (QSIG) standards have enabled the interoperability among PBXs that are interconnected via ISDN lines. Q.931 is an ISDN standard that enables the interconnection between PBXs and PSTN services. In turn, an organization can create a virtual PBX network that may encompass a collection of its own PBXs as well as centrex services across a wide geographic area (Stamper and Case 2003).

The growing demand for VoIP (discussed next) has manifested itself in a new generation of PBXs that interoperate with the Internet as well as with other data networks (Dooley 2005, 326). A traditional PBX included trunk lines connected to the PSTN (the local phone company or a long-distance carrier or both). Now a modern digital PBX can support IP telephony through an IP call manager that places and receives calls to and from the Internet. Such a PBX can connect the organization's voice and data traffic to the rest of the globe. With the use of intelligent network management systems, the organization's traffic is routed to the best connection, either over the PSTN or over the Internet, based on the nature of the traffic, the reliability of the network, the destination, and the cost of service (Beasley 2004, 411).

VOICE OVER INTERNET PROTOCOL

The convergence of voice and data communications took a major leap forward with the introduction of the Internet and its global access. In the past, modems were used to allow data to travel over the PSTN, a network that was created to carry exclusively for voice communication. Now, however, the Internet, which was created primarily to carry data, can now carry voice through a technology known as *voice over Internet protocol* (VoIP). VoIP enables digitized voice signals (or video for that matter) to be formatted in a manner similar to data packeting; these packets can then travel with data over the same physical network simultaneously (Black 2000, 13).

Many individual and corporate users alike started to use the Internet to place phone calls, bypassing completely local and long-distance phone companies, and hence reducing their phone bills. Those users employed the microphone and speakers on their personal computers (PCs) as voice communication input/output devices. Although these users were able to place and receive calls on their PCs, the voice quality was poor and unpredictable. The main reason for that was that the Internet's infrastructure and protocols allow individual packets to travel over the network through different physical paths, which may lead to delayed and possibly out-of-sequence arrival. With data transmission such as e-mail, that is not a problem because the recipient does not read the e-mail until the entire message has been delivered. On the other hand, voice and video traffic is time sensitive, requiring

that packets arrive in short and fixed time intervals in order to maintain proper audible quality.

The interest in VoIP provided a window of business opportunity for companies such as Vonage and Skype to move in and offer a higher-quality VoIP service. The market of VoIP service providers is rapidly growing, and they are gradually grabbing more and more customers away from traditional voice communications market leaders in local and long distance such as Verizon and Sprint.

COMPUTER TELEPHONY INTEGRATION

Computer telephony integration (CTI) combines two of the most widely used technologies in society today: the computer and the telephone. CTI serves numerous business applications such as telemarketing, technical support hotlines, and customer service centers. With CTI, businesses can advertise a nationwide toll-free number to their customers for placing orders, resolving products' technical problems, or questioning credit card charges. CTI uses an ACD unit or a PBX to examine incoming calls and identify the caller's telephone number, caller-entered account number, or type of service requested. It then uses that information to search a computer database for information on the identified caller, the product in question, or the credit card charge that is the subject of inquiry. As it routes the call to the most appropriate desk to handle the call, it also forwards to that desk's computer the relevant information that was obtained from the database.

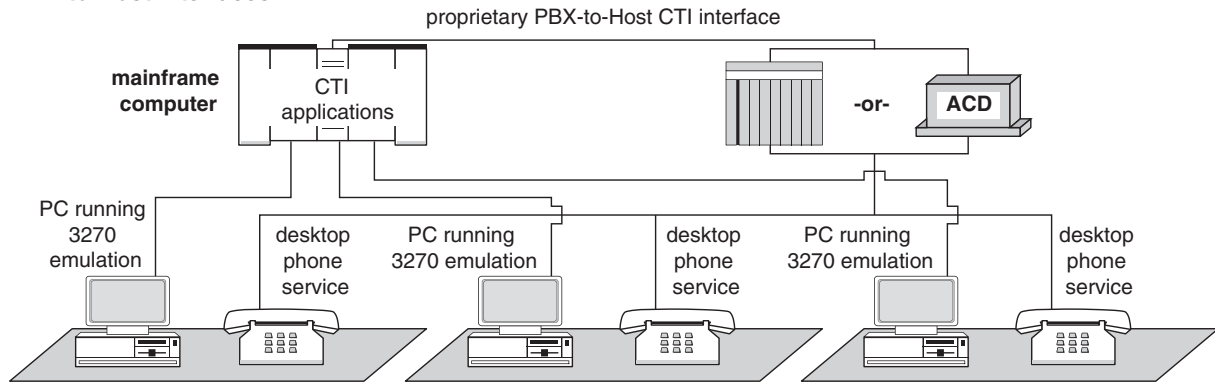

For example, a CTI system may use a caller's area code to identify the region from which the call originated and then route it to the appropriate regional sales office along with the caller's purchase history and credit limits that appear on the sales representative's computer screen as that call is routed to his or her desk. In other applications, using the caller-entered credit card number, a CTI system can retrieve the transactions history of that credit card, which can help the account representative answer the caller's questions efficiently and accurately. With CTI capability, the public can call a government agency and order specific forms which the system can automatically retrieve from its database and then forward the documents to a provided fax number or e-mail address.

One of the most useful features of CTI is the ability to provide users with a unified message box for all of their voice messages, e-mails, and text and video messages. With this feature, users can check one place—the computer screen—for all of their messages, which are marked by different icons to indicate the type of message received. Users can then read their e-mail or play recorded voice or video messages.

Architecture

CTI can be implemented on different scales using different platforms, depending on the size of the organization and type of application. A small business such as a

PBX-to-Host Interfaces

Desktop CTI

Client/Server CTI

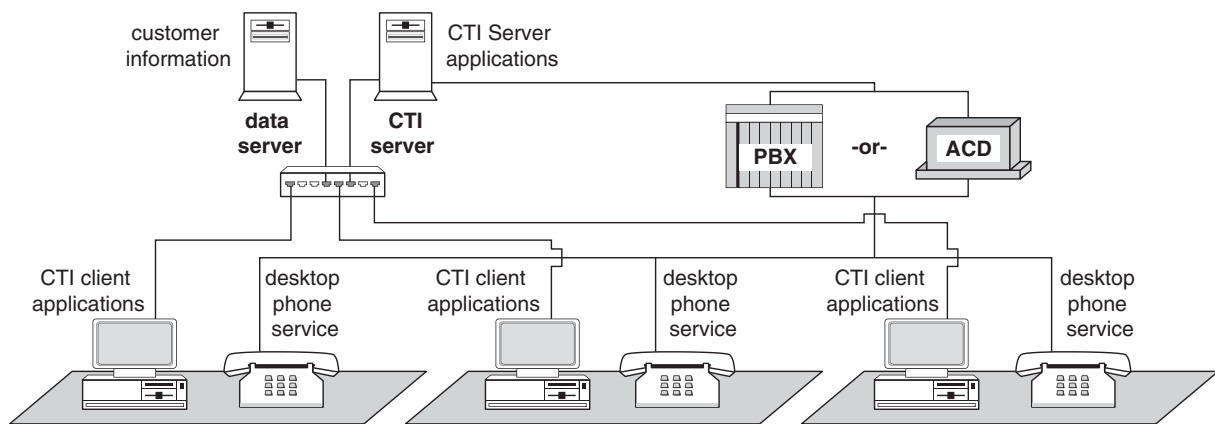

Figure 10: CTI architectures system. Source: Reprinted with permission from J. E. Goldman. 2004. *Applied data communication*. New York: John Wiley & Sons

fast-food outlet can benefit from a desktop-based CTI system. That system involves adding a CTI card to the personal computer, driver software, and a database management system on its hard drive. Although this is a scaled-down CTI system, it enables a store manager to relate a phone order to a customer in the store's database, identify his or her address, directions to the customer's premise, purchase history, and billing information.

A more common implementation of CTI in larger organizations could be based on mainframe or (single or multi-tier) client-server architecture, depending on the size of the organization, volume of transactions, and level of security desired (see Figure 10). The system could be distributed and internetworked to facilitate access by multiple sites.

CONCLUSION

Voice communications have always been an important aspect of human life. The invention of the telephone more than a century ago and all of the subsequent related technologies have made global voice communications a possibility for the first time in human history. Voice communication technology will continue to advance, and so will the dependence of society on it, from the individual chatting with friends to corporations conducting their business using voice communications systems. The advancements of such technologies will also continue to shape and reshape those enterprises whose business is facilitating voice communications infrastructure and all of its related services.

GLOSSARY

Automatic call distribution (ACD): Feature that can be provided by a PBX or stand-alone device that answers incoming calls and routes them to the most appropriate extension.

Central office (CO): A telephone company switching office where calls are routed to their appropriate designations.

Centrex: *A private branch exchange (PBX) service hosted by a telephone company in one of its central offices.*

Computer telephony integration (CTI): A technology that allows organizations to interface incoming calls with related data stored in the organization's database.

Dual tone multifrequency (DTMF): A dialing system that creates a signal with a unique frequency for each dialed digit.

Interexchange carrier (IXC): A telephone company (typically, a long-distance carrier) that carries phone traffic between local access areas.

Local access and transport area (LATA): A geographic region designated by the phone company for local calls.

Local exchange carrier (LEC): A telephone company that carries local phone traffic within a LATA.

Local loop: The connection between the customer premise and the local telephone company's central office.

Point of presence (POP): The central office where the interexchange carrier (IXC) is connected to the local access and transport area (LATA).

Private branch exchange (PBX): An on-site, privately owned switching facility.

Voice digitization: The process of converting voice analog signals into equivalent digital signals that can be transmitted by digital lines.

Voice over Internet protocol (VoIP): Using the Internet to carry digitized voice communications.

Wide area telecommunications services (WATS): A service that a business can subscribe to through a phone company to get a specific volume of calls at a highly reduced rate.

Public Switched Telephone Network (PSTN); Pulse Amplitude Modulation; Voice over IP (VoIP); Voice over MPLS and VoIP over MPLS.

INTRODUCTION

The word *facsimile*—from the Latin *fac* and *simile*, meaning “to make similar”—refers to the telecommunication technology used for transmitting graphical information over a distance. Also called *fax* for short, facsimile came into widespread use in the 1970s and 1980s following the standardization effort by the International Telegraph and Telephone Consultative Committee (CCITT, now known as ITU-T). The peak annual sales of fax machines reached twenty million units in the late 1990s. Today, an estimated seventy million fax machines have been installed worldwide, and twelve to fifteen million units are sold each year.

The fax machine is an indispensable part of many business establishments as a simple-to-use document transmission and messaging tool. Fax transmission works for both handwritten and printed documents, and a fax machine can be turned on around the clock to work across time zones. Today, close to half of all calls on the telephony network are estimated to be facsimile calls.

In the first part of this chapter, we describe the history, technology, and future of facsimile. We also discuss the future of facsimile in the increasingly Internet-centric telecommunication world.

HISTORICAL PERSPECTIVE

A less known fact in the history of telecommunications is that Samuel Morse’s 1844 patent on the telegraph was preceded by the patent for electrical facsimile in 1843 by

Scottish physicist Alexander Bain. Unlike the telegraph, which has transformed communications, facsimile saw limited commercial application in the nineteenth century. From the 1920s to the 1960s, facsimile was primarily a series of commercial failures: picture telegraphy by various post, telegraph, and telephone (PTT) administrations; Telefax by Western Union; fax broadcasting by newspapers and radio stations; and so on. Not until the 1970s did facsimile take root in the business application world in Japan and the 1980s that it found worldwide adoption. In the first part of this chapter, we provide a historical perspective on the development of the facsimile technology from the 1840s to its modern embodiment in the telephony network-based group 3 standard and data network-based group 4 standard.

Ancient Telegraphy

The story of the runner who died from exhaustion after delivering the message of victory from Marathon to the Greeks in Athens in 490 B.C. is frequently used to illustrate the desirability of finding less arduous means for telecommunications. From the ancient world to the present, drums, torch and smoke signals, homing pigeons, and semaphores have been used to convey messages over long distances. A network of water telegraph systems was installed throughout the Roman Empire by 150 B.C. These water telegraph systems used the draining of water from water tanks as timers so that durations of specific drum or torch signals could be timed and specific messages

conveyed. The invention of the telescope in the early seventeenth century pushed forward the development of optical telegraphy, also called *semaphore*, which is based on the arrangement of flags, lights, or mechanical arms installed in towers that can be seen from a distance. In the late eighteenth century, a French system by Claude Chappe was adopted and widely deployed in Napoleon's empire. Chappe's system, which was based on mechanical arms that could be rapidly rearranged by ropes and pulleys, achieved rates of communications that were comparable to those achieved by the earliest electrical telegraphs.

Electrical Telegraphy and Early Facsimile

The idea of electrical telegraphy came to Samuel Morse in 1832. His successful demonstration of the telegraph to the U.S. Congress in 1844 heralded the age of electrical communications. Morse's invention is significant not only in the apparatus but also in his concept of a code that uses sequences of dots and dashes to represent the alphabets. Morse introduced the notion of an efficient code by assigning shorter sequences to the more commonly used letters of the alphabet.

Although Morse's telegraph was focused on transmitting alphabets, the facsimile system was pursued around the same time for the transmission of handwritings and drawings. In fact, in 1843, one year before Morse's patent, an English patent was issued to Scottish physicist Alexander Bain for his "recording telegraph," the first known design of a facsimile system. Bain's system used a battery-driven electric pendulum clock. At the transmitter, on each swing of the pendulum, a stylus traced across a metal typeface, making and breaking an electrical circuit. At the receiver, a similar pendulum and stylus traced over a damp electrolytic paper that was blackened whenever there was a current flow, producing a marking that represented a reproduction of the raised typeface.

In 1848, English physicist Frederick Bakewell obtained the patent for an alternative facsimile machine design. Bakewell's design differed from Bain's in two ways. First, instead of the pendulum, Bakewell used a rotating drum with leadscrew to perform the mechanical "scanning." The rotation of the drum was driven through a gear train by a weight that was lowered by gravity. Second, instead of a typeface, an insulating ink on a metal surface was used at the transmitter.

Bain's and Bakewell's designs were both hampered by the difficulty in achieving good synchronization between the transmitter and receiver. Bain's pendulum system used a synchronizing electrical pulse and a latch magnet to start and stop each pendulum swing. This synchronization system was prone to lightning and atmospheric disturbances that might induce current pulses on the line. Bakewell never fully resolved the synchronization problem for his drum-based design.

In 1861, an Italian named Giovanni Caselli patented the *pantelegraph*, a facsimile machine design that was based on both a pendulum and a drum. The pantelegraph made use of the leadscrew to move the stylus by one line for each pendulum swing. As with Bakewell's machine, the image to be transmitted was drawn with an insulating

ink on a metal surface. Caselli adopted Bain's electric clock system for synchronization and introduced improvements that would eliminate most errors resulting from extraneous current pulses. The pantelegraph was received with such great enthusiasm in Paris that the Pantelegraph Society was created to prepare for its full exploitation. Customers from as far away as the imperial court of China came to observe the system's demonstration. In 1865, the world's first commercial facsimile service commenced operation between the French cities of Paris and Lyon. Unfortunately, despite an enthusiastic beginning, the pantelegraph did not live up to its full potential. First, the Pantelegraph Society failed to seize the opportunity to vigorously promote the device; instead it waited passively for orders to arrive. Second, the pantelegraph was invented just when the world was investing heavily in the telegraph network. In France, Chappe's semaphore network was being replaced by the telegraph. The French Telegraph Administration, concerned that the pantelegraph might jeopardize its investment in the telegraph network, imposed a heavy tariff on the pantelegraph service for the transmission of written messages, intending that pantelegraph service would be limited to the transmission of drawings and signatures, services that could not be performed by the telegraph. In Italy, the pantelegraph faced similar political obstacles. Eventually, in 1870, the pantelegraph service was discontinued. Caselli died, disappointed, in 1891.

The pantelegraph was an ingenious design in its time. Working units of the pantelegraph still exist in museums today. Units kept at the Musée National des Techniques and the Postal Museum in France were turned on in 1961 and 1982; as reported in an article in the June 1995 issue of *La Revue*, a publication of the Musée, the units "operated faultlessly, six hours a day, for months." The museum units operated at a speed of 120 lines per minute. Figure 1 shows a working pantelegraph and its scanning unit. The device stands more than 2 meters tall.

The facsimile systems introduced by Bain, Bakewell, and Caselli were all based on mechanical contact scanning by a stylus. In 1902, Arthur Korn of Germany introduced the first facsimile device based on optical scanning. In Korn's system, the film negative of a photograph was put on a revolving glass drum inside a cylinder. Light from a transmitter lamp was focused on the film, passing through the film as well as the glass drum, and reflected by a prism onto a selenium cell that produced a current in response. The receiver was also based on photographic recording on film. As relays and spark gap modulators were found too slow to be varying light sources for recording, Korn developed an electromagnetic light shutter that was a piece of aluminum foil hung by a loop of wire in a magnetic field. The flow of current deflected the aluminum foil and blocked or passed the light from the receiver lamp that was focused on the foil. In 1904, Korn sent telephone wire photos from Munich to Nuremberg, a distance of more than 600 miles. In 1907, Korn sent the first wire photos from continent Europe to England. In 1922, a photo of Pope Pius XI was sent from near Rome to Berlin and then radioed to a navy radio station in Maine, United States. The transmission of this picture took forty minutes. Later, Korn developed a radio system

Figure 1: Pantelegraph. Source: Retrieved from <http://chem.ch.huji.ac.il/~eugenik/history/caselli.html>.

so that maps, sketches, and aerial photos could be sent from aircraft in what was called a “phototelegraph.”

Shortly following Korn, Edouard Belin (1876–1963) of France constructed in 1907 and perfected by 1925 an alternative optical-based system, the Belinograph. Belin’s system operated not on the film negative but directly on the image that was placed on a cylinder and scanned with a powerful light beam. The reflected light was converted into electrical current. The Belinograph, widely used in Europe by the news media in the 1930s and 1940s, formed the basic principle of all subsequent facsimile machines (Through the Wires, no date).

Early Applications and Failures

During the years between the first and second world wars, many commercial fax operations were launched. World War I brought great progress to electronics and radio, and along came improved facsimile system designs such as Bartholomew and MacFarlane’s Bartlene system (1920), AT&T’s telephotography machine (1924), RCA’s Photoradio (1924), and various designs by Western Union (1924 and later). According to an AT&T study, eighteen different facsimile systems were operational or in development in 1928.

In the Bartlene system, a screen image was first created according to the same principle used in newspaper printing: gray scale was represented by dots of different sizes. The sizes of the dots were then transmitted as a telegraph message over the standard Western Union telegraph cable. As such, the Bartlene system was a digital system.

AT&T’s telephotography machine operated on similar principles as Korn’s machine and was one of the first systems that operated over the telephone network using conditioned private lines. To achieve synchronization, the drum and motor was in a servo frequency control loop using an accurate tuning fork, housed in a constant temperature oven, for frequency reference. The telephotography machine (see Figure 2) was used mainly to transmit newspaper wire photos such as photographs of Babe Ruth.

The RCA system was based on radio transmission. Similar to AT&T’s system, the RCA system employed a tuning fork in a constant temperature oven. An amplifier took the tuning fork frequency reference and generated the current for driving the motor. Amplitude of the scanned signal was converted into the duration of an on-off RF signal, a process known as *constant frequency variable dot* (CFVD) modulation.

Figure 2: AT&T’s telephotography machine. Source: Retrieved from www.att.com/atllabs/reputation/timeline/24fax.html.

Fueled by competition in news reporting, facsimile was widely used for the transmission of pictures worldwide by the late 1920s. Services were provided by European PTTs, AT&T, and news agencies such as the Associated Press, NEA Acme, Reuters, and *The New York Times*. But these services were never profitable in terms of business. They faced competition from the less timely but far cheaper alternative: airmail. Although European PTTs were keeping money-losing businesses alive to maintain the capability, AT&T sold its Wirephoto business to Associated Press in 1934. The start of World War II virtually finished off all public picture facsimile services because of the lack of countries to communicate with (Coopersmith 1993, 1994).

During this time, facsimile was also used to transmit maps, terrain drawings, and weather charts. During World War II, such uses were adopted in a widespread fashion by both sides. In 1955, the U.S. Weather Bureau developed a weather facsimile network using dedicated leased lines for transmitting weather data around the country.

Western Union was a major developer and user of facsimile from the 1930s to 1960s. The company's approach, interestingly, was to make facsimile an extension of the telegraph. Facsimile offered to Western Union the potential of error avoidance and cost saving by eliminating telegraph operators. Facsimile equipment between its own offices and the offices of its large customers also allowed Western Union to deliver telegrams without a courier. Figure 3 shows a DeskFax system that was developed by Western Union in 1935. The DeskFax was the first large-scale deployment of facsimile. Eventually, more than 50,000 units were in customer offices in the 1950s. Fax services accounted for \$42 million of Western Union's \$255 million revenue in 1958.

In the 1960s, in the face of rapidly changing technology, Western Union's refusal to treat and develop facsimile as an independent service caused DeskFax to eventually disappear from the scene.

Another noteworthy episode in the history of facsimile was fax broadcasting. Before and after World War II, newspapers and radio stations cooperated to introduce radio facsimile receivers into individual homes so that newspapers could be broadcasted into the home anytime during the day. By 1940, forty stations in the United States were experimenting with nighttime fax broadcasting

Figure 3: DeskFax. Source: Retrieved from www.westernunion.gr/netemts/HISTORYPHOTO.HTM.

of newspapers. This effort was interrupted by the war but was renewed afterward. In 1948, the FCC created a new radio facsimile standard based on FM instead of AM. It supported 4-inch- and 8-inch-wide facsimiles, with synchronization provided by 60 hz power lines. Fax broadcasting eventually died because of the high cost and unpleasant smell of the recording paper, as well as the insufficient quality of the received newsprint.

Modern Systems: Timelines for Group 1 to 4 Standards

The trigger that led to the widespread adoption of facsimile in the 1980s was the adoption of a standard protocol for sending faxes at a rate of 9600 bps in 1980. This standard is known as the *group 3 standard*. Later, a group 4 standard emerged that was designed to work over ISDN lines. Because the widespread deployment of ISDN has never materialized as initially envisioned, group 4 facsimile has never taken off and the group 3 standard continues to drive facsimile operation today. Group 3 is a digital standard. Before group 3, the group 1 and group 2 analog standards existed but were not universally adopted by manufacturers. Before group 3, the facsimile world was characterized by incompatible machines and limited deployment. In this section, we provide a brief timeline for the development of modern facsimile standards.

In the United States, the Electronic Industries Association (EIA) established the TR-29 technical committee to work on the facsimile standard in 1962. The effort was not fully embraced by the participants, who were hesitant to disclose their designs and accept proposals that would require them to modify their designs. Nevertheless, in 1966, EIA published Standard RS-328, *Message Facsimile Equipment for Operation on Switched Voice Facilities Using Data Communication Equipment*, a set of standards that allowed a high degree of tolerance together with a recommended "eventual standard." This was the first U.S. standard. Although few manufacturers upgraded to the eventual standard, with RS-328, a large number of machines from different manufacturers could begin to interoperate, even though pages might be stretched or have their edges cut off. The common speed was 6 minutes per 8.5×11 -inch page.

CCITT (now ITU-T) began the group 1 international standard effort in 1968 based on RS-328 and adopted the final standard in 1974 with minimal participation from U.S. companies. Although RS-328 used *frequency modulation* (FM) with 1500 hz representing "white" and 2400 hz representing "black," the group 1 standard specified 1300 hz as "white" and 2100 hz as black. The scanning speed for group 1 was four minutes per page.

Following what happened at CCITT, U.S. manufacturers began to work together more closely in the TR-29 meetings. Companies such as Xerox and Graphic Sciences were developing faster systems that offered group 1 transmission quality. Xerox's design also was based on FM but Graphic Sciences' design was based on *amplitude modulation* (AM), which allowed the transmission of gray scale. Working through a U.S. Department of State CCITT group, U.S. manufacturers were much better represented at CCITT. With good collaborative support from the

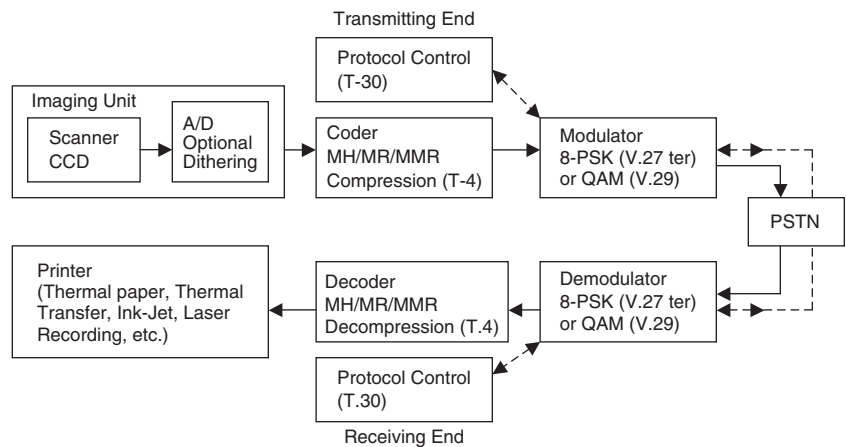

Figure 4: Block diagram of a group 3 fax machine

British Facsimile International Consultative Committee (BFICC), the group 2 standard adopted in 1976 opened the door to a true global standard. Group 2 was based on *amplitude modulation-phase modulation with vestigial side-band* (AM-PM VSB) at a carrier frequency of 2100 hz; it allowed a transmission speed of three minutes per page.

It was also in the mid-1970s that the sophistication and cost of the three underlying technologies for facsimile improved to a reasonable level. During the 1960s, the center of activities for facsimile had shifted to Japan. Fax machines first had become popular there, where the use of *kanji* (a system of writing using Chinese characters) made typing difficult; it was much faster to handwrite kanji, which gave facsimile transmission an advantage. It was also the Japanese who first mastered the skill for efficient and low-cost manufacturing. Following the group 2 standard, Japanese manufacturers became dominant players in the global market.

Group 3 fax is today's dominant facsimile standard. Its standardization effort began in 1975, around the same time that the group 2 standard was adopted. Group 3 (G3) is a digital standard, and operation of a group 3 facsimile system no longer depends on the synchronization between transmitter and receiver. Adoption of group 3 occurred in 1980 and led to the widespread adoption of facsimile in the office and home in the 1980s. The group 3 standard includes modulation schemes, an end-to-end digital control protocol, variable transmission rates, coding schemes for data compression, and error control. Generally, G3 fax achieves a transmission rate of one minute per page.

The group 4 facsimile standard was adopted in 1984. It was intended for use over the new *public switched data network* (PSDN) based on ISDN. It also adopted the *open system interconnection* (OSI) layered model for computer communications. It defined classes of machines with different levels of capabilities, covered transmission over different networks, and included other services such as Telex. Instead of being a pure image, a document to be transmitted in group 4 may contain a layout structure with text as well as graphics. Many of the features defined for group 4 facsimile were also adopted as options for group 3. Like ISDN, group 4 fax was never widely deployed.

In the 1990s, with the mass adoption of personal computers and peripherals, new facsimile standards for the Internet-centric world came to the scene. These included

the PC fax and T.38. As of today, group 3 fax remains the main staple of facsimile. It is the easiest to use and an indispensable form of communications for many businesses and households.

In the remainder of this chapter, we will discuss the technology involved in groups 3 and 4 facsimiles, as well as emerging Internet-centric standards.

GROUP 3 FACSIMILE

Overall Architecture

The block diagram of a group 3 fax machine is shown in Figure 4. Components include an image scanner with an analog-to-digital converter (ADC), a coder-decoder, and a modem. At the transmitting end, the imaging unit converts a document into a digital image, and then the coder compresses the image to reduce the number of bits that need to be transmitted; the modulator sends the compressed data over a telephone line. At the receiving end, the demodulator recovers the compressed and transmitted data, the decoder expands the compressed data, and the printer produces a duplicate of the original document (ITU-T 1988, 2003).

The resolution specified for group 3 fax is 1728 pel* per standard scan line of 215 millimeter (mm) \pm 1 percent horizontally and 3.85 lines per mm \pm 1 percent vertically. The standard vertical resolution of G3 is identical to that of G1 and G2 faxes. Horizontally, although G3 is a digital system, G1 and G2 are analog systems and are not represented by pels. Options for $2 \times$ and $4 \times$ vertical resolutions and wider horizontal scan-line width, higher horizontal resolutions, or both are also allowed. Standard G3 focuses on the transmission of halftone images so that each pel is either a black or white—that is, either 0 or 1. A dithering scheme may be used with the ADC so that any gray scale in the original picture can be reflected by the density of black pels. For printing, a variety of recording technologies are available today. The imaging and printing system will be discussed in the next section.

The raw digital image is compressed by a coder using either a one-dimensional *modified Huffman* (MH)

*A discrete, metrically measured picture element.

code or a two-dimensional *modified READ*** (MR) code. These codes utilize two facts: (1) Most fax images contain large numbers of continuous white pels, and (2) there are usually few changes between two successive scan lines. At the receiver, the compressed data are decompressed. Because errors may occur in the transmission, error-correction and error-concealment schemes are used to minimize their impact.

Modulation methods can be:

- 2.4 or 4.8 Kbps *phase shift keying* (PSK), according to V.27ter, when operating over the general PSTN;
- 7.2 or 9.6 Kbps *quadrature amplitude modulation* (QAM), according to V.29; or
- 9.6 Kbps or 14,400 *trellis modulation*, according to V.17, when the facsimile is operating a high-quality switched circuit or leased line.

The procedures for communications between a transmitting fax machine and a receiving G3 fax terminal over the PSTN are governed by a set of protocols specified in Recommendation T.30 by ITU-T (2005). Procedures involved include:

- call establishment and call release;
- compatibility checking, status, and control command;
- checking and supervision of line conditions; and
- control functions and facsimile operator recall.

A fax terminal may be *automatic* in that it is capable of performing all of the procedures above, or it may be *manual* in that some of the procedures may require actions to be taken by an operator. Procedures are specified for all combinations of automatic and manual transmitting and receiving terminals. Communications of control information between terminals are based on frequency tone signals as well as binary coded signaling. The binary coded signaling is based on *high-level data-link control* (HDLC).

Various annexes were added to the T.4 (ITU-T 2003) standard to provide enhancements to G3 fax, including:

- a. optional error-correction mode;
- b. optional file-transfer mode to permit the transmission of any data file;
- c. optional character mode to permit the transmission of character-coded documents based on the T.30 standard for transmitting character-coded control data;
- d. optional *mixed mode* (MM) to permit the transmission of both character-coded and facsimile-coded data;
- e. optional continuous-tone color mode;
- f. facsimile group 3 64-kbps option F (G3F) for operation over ISDN;
- g. transmission of color and gray-scale images using lossless coding scheme;
- h. *mixed raster content* (MRC) mode; and
- i. optional continuous-tone color mode.

Imaging and Printing

A standard G3 facsimile terminal supports the following paper sizes: ISO A4, ISO B4, ISO A3, North American letter (215.9 mm × 279.4 mm) and legal (215.9 mm × 355.6 mm). The pel density of G3 facsimile is “unsquare,” unlike that of the square G4. The T.4 standard has now focused on the metric-based pel, and specifies:

- a. a standard resolution of 3.85 lines/mm ±1 percent in vertical resolution;
- b. optional higher resolution of 7.7 lines/mm ±1 percent and 15.4 lines/mm ±1 percent in vertical direction;
- c. 1728 black and white picture elements along the standard scan line length of 215 mm ±1 percent;
- d. optionally, 2048 black and white picture elements along a scan line length of 255 mm ±1 percent;
- e. optionally, 2432 black and white picture elements along a scan line length of 303 mm ±1 percent;
- f. optionally, 3456 black and white picture elements along a scan line length of 215 mm ±1 percent;
- g. optionally, 4096 black and white picture elements along a scan line length of 255 mm ±1 percent;
- h. optionally, 4864 black and white picture elements along a scan line length of 303 mm ±1 percent.

Imaging

Drum scanners were broadly used in the past. In the drum scanner, the scanning spot traces horizontally (or *helically*) across a page as the drum turns. Brightness information on the page is converted by a photosensor into a signal one spot at a time. This spot corresponds to a *pel* in the case of a halftone (black-and-white) image and a *pixel* in the case of gray-scale or color images.

A modern scanner used in G3 typically works on more than one spot at a time. An array of 1728 or more tiny *charge-coupled device* (CCD) photosensors focuses on all spots across a horizontal line on the page simultaneously so that a document can be scanned one line at a time. The number of photosensors is scaled proportionally to the page width and supported resolution. In this way, a document can be scanned far more quickly. The photosensor array can be implemented on a small CCD chip in the case of a camera-style scanner, or it can be implemented along a bar of the same width as the document in the case of a contact image scanner.

The disadvantage of the camera-style scanner is its large size: An optical path distance of approximately 30 centimeters (cm) is needed to focus light from the illuminator reflecting off the scanned page onto the CCD chip through a lens with a 10:1 image reduction. A mirror system can be used to fold the optical path and reduce the size of the scanner. For the contact scanner, an array of integrated *light-emitting diodes* (LEDs), photosensors, and lenses distributed along a bar is placed directly above the scanned document. The LEDs illuminate the picture elements, and the photosensors detect the reflected light. The contact scanner allows for a more compact design and provides uniform image quality without distortion at the edges of the page. The LEDs demand much lower power (Streetman and Banerjee 2006).

**An acronym for *relative element address designate*.

The photosensor works by accumulating a voltage in proportion to the amount of light incident on it. During scanning, each photosensor's voltage is read and converted to a single-bit digital value by an ADC. A 0 bit represents a white pel, and a 1 bit represents a black pel. An *automatic background control* circuit is used in most group 3 terminals so that any off-white background of the original will not be converted into black. The original group 3 standard was intended for transmitting bilevel textual images. The printing technology in the 1980s was also bilevel. The technique of dithering was frequently used to enhance the quality of the resulting digital image from the scanning process. We will describe the process of dithering in a later section.

Printing

We now discuss several printing technologies that are most commonly used in fax terminals.

The invention of thermal paper recording brought significant improvements over earlier technologies such as electrolytic paper and contributed to the widespread adoption of fax. It provided better image contrast, did not fade, cost less, and did not emit an unpleasant odor as did electrolytic paper. Thermal paper is coated with a dye and an oxidized material on a base. Upon heating, the dye and the oxidized material fuse and produce a mark. In a thermal paper printer, the printer head is made up of a row of small resistor-based heating elements. The supply of a current pulse provides the heating needed to produce the mark on the paper. One disadvantage of thermal paper recording is that the recorded image deteriorates if the paper is later exposed to heat.

Thermal-transfer recording works according to principles similar to thermal-paper recording, with the difference that the heat is applied to a transfer film over a plain white paper so that the dye is transferred to the white paper. The thermal-transfer printer costs more than the thermal-paper printer, and the recording materials ("ink") used also cost more, but the printer uses standard paper that can be conveniently handled and is not sensitive to heating and light.

The laser printer and the LED printer are both based on similar electrostatic principles. In the laser printer, a rotating mirror scans a laser beam across the recording paper and produces an electrostatic charge on each spot on the paper. The presence of an electrostatic charge causes the recording material (the "toner") to adhere to the spot, and as the paper rolls out of the printer, a "fuser" applies heat to the paper and melts the toner into the paper. In an LED printer, an array of LEDs is used instead of a scanning laser beam. Figure 5 shows the major component in a laser printer.

Ink-jet recording has been most widely adopted in desktop PC printing. Earlier ink-jet printers appeared long before group 1 fax terminals but were not popular because of the effort needed both to clean print heads to prevent clogging and to refill ink reservoirs. Widespread success came with the availability of replaceable cartridges and print jets. Although the ink-jet printer costs less than a laser or LED printer, the per-page cost is much higher.

Figure 5: Major component in a laser printer

Coding

Consider a binary image at a resolution of 1728 pels per line and 1068 lines per page (3.85 lines per mm with a page length of 277 mm) created from the scanning process of a G3 terminal. Uncompressed, 1,845,504 bits are needed to represent this image, and it will take 384 seconds (more than 6 minutes) to transmit this image over a phone line at 4800 bps. The scanned image, however, typically contains redundant information and can be compressed significantly.

The modified Huffman code noted earlier is used by all G3 fax terminals. Two variations—the *modified READ* (MR) code and *modified modified READ* (MMR) codes—are supported as options. A newer coding scheme is *trellis coding*. These coding methods reduce the amount of data to be sent over the phone lines and therefore the time needed to send each page. We first describe the modified Huffman and modified READ coding schemes.

Modified Huffman Coding

The MH coding scheme is a so-called one-dimensional coding scheme as one line of data is scanned and coded for transmission at a time. In contrast, in MR coding each line is scanned and compared to the previous line. The coder encodes only the changes. The MR coding achieved greater compression than MH but is less robust against transmission errors. Both schemes make use of the fact that there are typically long strings of 0's and 1's in a scanned line or in the difference between the current line and the previous line.

In MH, a line is decomposed into alternating white runs and black runs (strings of 0's and strings of 1's) that sum to 1728 bits (at standard resolution). Each code word represents a run-length of either all white pels or all black pels, and the code table is designed so that more likely run lengths are assigned shorter code words. To maintain color synchronization, all data lines begin with a white run-length code word. A white run length of zero is sent if the actual scan line starts with a black run. Two types of code words are used: *terminating code words*, which encode values from 0 to 64; and *makeup code words*, which encode values in multiples of 64. Hence, a run length is encoded either by one terminating code word or a makeup code word followed by a terminating code word. The white run lengths and the black run lengths should sum to 1728 for each line. To provide error checking, an *end-of-line* (EOL) code word is also included. The sum of the run lengths between two EOL code words should equal 1728. Any discrepancy is an indication of transmission errors. Table 1 shows extracted portions of tables in ITU-T Recommendation T.4.

Table 1: Extracted Portions of Tables in from ITU-T Recommendation T.4 (2003)**Tab.1 T.4 – Terminating codes**

EOL	000000000001	EOL	000000000001

NOTE: It is recognized that terminals exist which accommodate larger paper widths maintaining the standard horizontal resolution. This option has been provided for by the addition of the make-up code set defined in this table.

Tab.1 T.4 – Make up Codes

Run length (black and white)	Make-up codes
1792	00000001000
1856	00000001100
1920	00000001101
1984	000000010010
2048	000000010011
2112	000000010100
2176	000000010101
2240	000000010111
2304	000000010111
2368	000000011100
2432	000000011101
2496	000000011110
2560	000000011111

NOTE: Run length in the range of lengths longer than or equal to 2624 pels are coded first by the make-up code of 2560. If the remaining part of the run (after the first make-up code of 2560) is 2560 pels or greater, additional make-up code(s) of 2560 are issued until the remaining part of the run becomes less than 2560 pels. Then the remaining part of the run is encoded by terminating code or by make-up code plus terminating code according to the range as mentioned above.

Modified READ Coding

The MR is a lossless two-dimensional coding technique for bilevel images, a superset of the modified Huffman code. It is used by many facsimile terminals.

In MR, we define a *changing element* as an element with a color (i.e., black or white) that is different from

that of the previous element on the same line. It was estimated that 75 percent of changing elements occur within one position to the left or right of a corresponding changing element in the previous line. In MR, the position of each changing element in the current line is encoded with respect to the position of a corresponding reference

Table 2: Modified READ Coding

Code	Explanation
a_0	The reference or starting changing element on the coding line. At the start of the coding line, a_0 is set on an imaginary white changing element situated just before the first element on the line. During the coding of the coding line, the position of a_0 is defined by the previous coding mode.
a_1	The next changing element to the right of a_0 on the coding line.
a_2	The next changing element to the right of a_1 on the coding line.
b_1	The first changing element on the reference line to the right of a_0 and of opposite color to a_0 .
b_2	The next changing element to the right of b_1 on the reference line.

element either on the previous line or on the same line. Because transmission errors will lead to error propagation to subsequent lines, a K parameter is defined to limit the number of successive lines that can be coded two-dimensionally. A maximum K value is defined under different vertical resolutions:

- Standard vertical resolution: $K = 2$
- Optional higher vertical resolution:
 - 200 lines/25.4 mm, $K = 4$
 - 300 lines/25.4 mm, $K = 6$
 - 400 lines/25.4 mm, $K = 8$
 - 600 lines/25.4 mm, $K = 12$
 - 800 lines/25.4 mm, $K = 16$
 - 1200 lines/25.4 mm, $K = 24$

To explain how MR coding works, we define the following elements with reference to Table 2.

At any instance, the MR encoder chooses one of three coding modes based on the relative positions of the changing elements defined in Table 2. The *pass mode* is identified when b_2 lies to the left of a_1 . When this occurs, a_0 is set immediately below b_2 (to a'_0) in preparation for the next coding (see Figure 6).

The *vertical mode* is identified when b_2 does not lie to the left of a_1 and the distance $|a_1b_1|$ is less than or equal to 3 (see Figure 7). In this case, we encode the distance

**Figure 6:** Pass model**Figure 7:** Vertical model

a_1b_1 by one of seven values: $V(0)$, $V_R(1)$, $V_R(2)$, $V_R(3)$, $V_L(1)$, $V_L(2)$, and $V_L(3)$. The subscripts R and L indicate whether a_1 is to the left or to the right of b_1 . After the encoding occurs, the position of a_0 is reset to a_1 .

If b_2 does not lie to the left of a_1 but the distance $|a_1b_1|$ is greater than 3, then the horizontal mode is identified (see Figure 8). In this case, we encode both the run lengths a_0a_1 and a_1a_2 using the code words $H + M(a_0a_1) + M(a_1a_2)$, where H is the flag code word 001 taken from the two-dimensional code table, and $M(a_0a_1)$ and $M(a_1a_2)$ are code words that represent the length and "color" of the runs a_0a_1 and a_1a_2 , respectively, and are taken from the appropriate white or black one-dimensional uncompressed code tables (see Table 1). Note that an entrance code precedes the uncompressed code. After a horizontal mode encoding, the position of a_0 is set on a_2 .

Table 3 shows the two-dimensional code table from ITU Recommendation T.4 (2003). Figure 9 shows the flowchart that specifies the coding procedure. The one-dimensional uncompressed code table, also from T.4, is shown in Table 4.

The modified modified READ (MMR) codes are part of the group 4 facsimile standard and will be described in the enhancement section.

Protocol

As discussed earlier, a fax terminal is automatic if it is capable of performing all of the protocol procedure without operator action. Otherwise it is considered manual. ITU-T Recommendation T.30 (2005) classifies eight operating methods as shown in Table 5.

Note that while the direction of fax transmission is usually from the calling terminal to the called terminal,

**Figure 8:** Horizontal mode

Table 3: Two-Dimensional Code Table

Mode	Elements to be coded		Notation	Code word
Pass	b_1, b_2		P	0001
Horizontal	a_0a_1, a_1a_2		H	$001 \div M(a_0a_1) \div M(a_1a_2)$ (Note 1)
Vertical	a_1 just under b_1	$a_1b_1 = 0$	$V(0)$	1
	a_1 to the right of b_1	$a_1b_1 = 1$	$V_R(1)$	011
		$a_1b_1 = 2$	$V_R(2)$	000011
		$a_1b_1 = 3$	$V_R(3)$	0000011
	a_1 to the left of b_1	$a_1b_1 = 1$	$V_L(1)$	010
		$a_1b_1 = 2$	$V_L(2)$	000010
		$a_1b_1 = 3$	$V_L(3)$	0000010
Extension	2-D (extensions) 1-D (extensions)			0000001xxx 000000001xxx (Note 2)

Note 1 – Code M() of the horizontal mode represents the code words in Tables 2 and 3.

Note 2 – It is suggested the uncompressed mode is recognized as an optional extension of two-dimensional coding scheme for Group 3 terminals. The bit assignment for the xxx bits is 111 for the uncompressed mode of operation whose code table is given in Table 5.

Note 3 – Further study is needed to define other unspecified xxx bit assignments and their use for any further extensions.

Note 4 – If the suggested uncompressed mode is used on a line designated to be one-dimensionally code, the coder must not switch into uncompressed mode following any code word ending in the sequence 000. This is because any code word ending in 000 followed by a switching code 000000001 will be mistaken for an end-of-line code.

Source: ITU-T Recommendation T.4.

the standard also allows for transmission from the called terminal to the calling terminal.

The time sequence of a facsimile call consists of the following five phases.

Phase A: Call establishment

Phase B: Premessage procedure (with an identification section and a command section)

Phase C: Message transmission (includes phase C1, in-message procedure; and phase C2, message transmission)

Phase D: Postmessage procedure

Phase E: Call release

The time sequence of a facsimile call is shown in Figure 10.

Each of the eight operating methods requires a slightly different procedure sequence. Here we provide a high-level description of the procedure sequence under method 4-T, where an automatic terminal calls an automatic terminal and the direction of facsimile transmission is from calling terminal to called terminal.

Phase A: Call Setup

The sending terminal dials the receiving terminal through the PSTN and sends the *calling tone* (CNG) that indicates that the call is from a fax terminal. CNG is a 1100-hz beep at a 0.5 second on, 3 second off cycle. The called terminal answers by going off-hook and, after a 0.2 second delay, sends back to the calling terminal the *called terminal identification* (CED) answer tone. CED is a continuous

2,100-hz +15hz tone with a duration exactly between 2.6 and 4 seconds.

Phase B: Premessage Procedure

The receiving terminal sends its *digital identification signal* (DIS) at 300 bps to declare its capabilities and options supported such as:

- modem types supported,
- resolution,
- coding scheme for compression,
- maximum paper length,
- minimum time needed to record a scanned line at the receiver, and
- nonstandard features.

The calling terminal then sends a *digital command signal* (DCS) to lock the receiving terminals into the selected capabilities and options followed by an all-zeros 1.5-second training signal (TCF) for the data modem. After its modem is trained, the receiving terminal is ready and sends a *confirmation-to-receive* signal (CFR).

Phase C: Message Transmission

The calling terminal sends a training signal again, followed by the image data for the entire page.

Phase D: Postmessage Procedure

The calling terminal sends a *return-to-control* (RTC) signal and switches the modem back to 300 bps. If no more

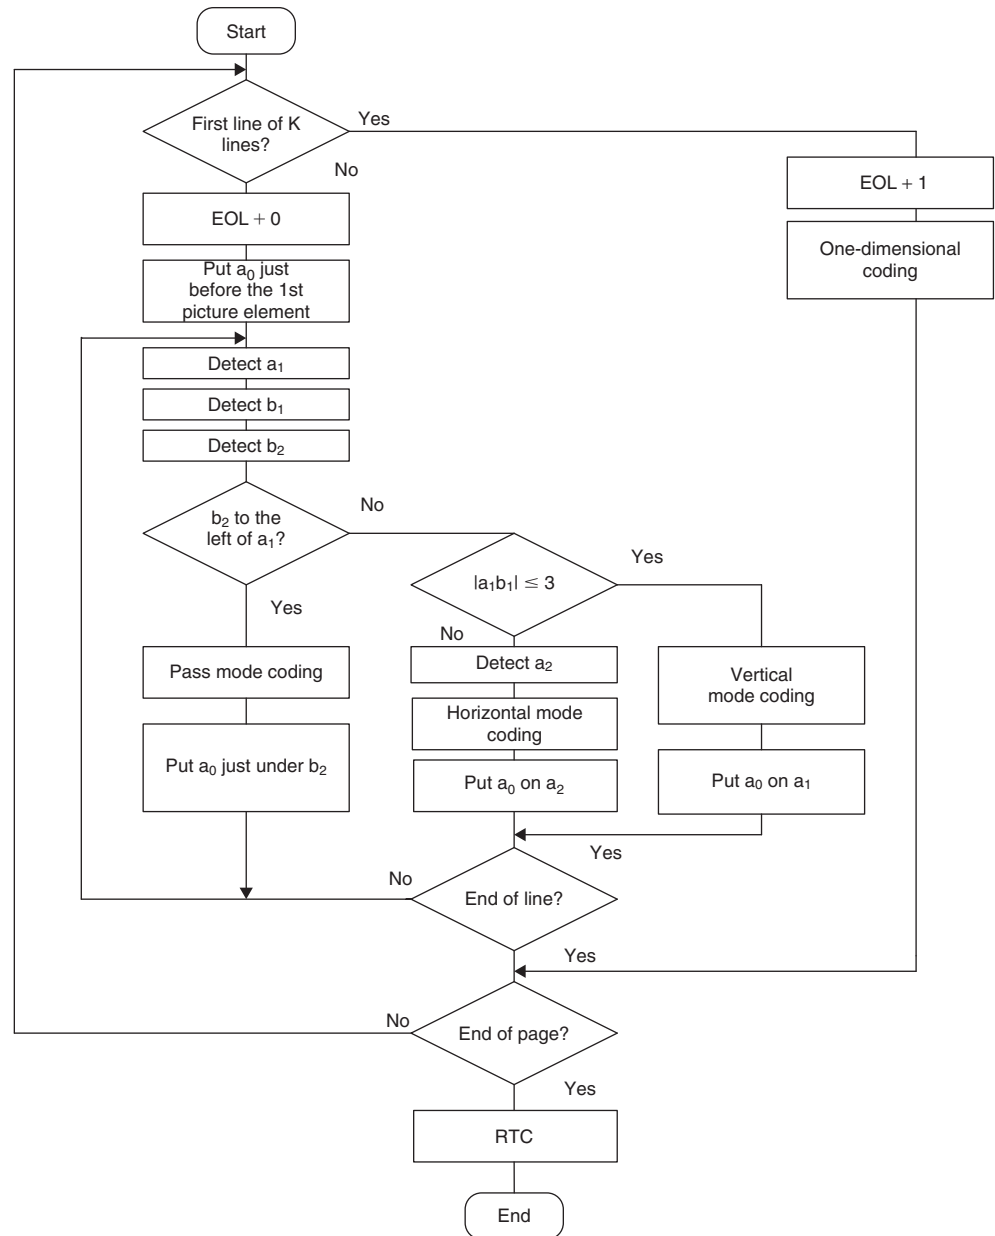

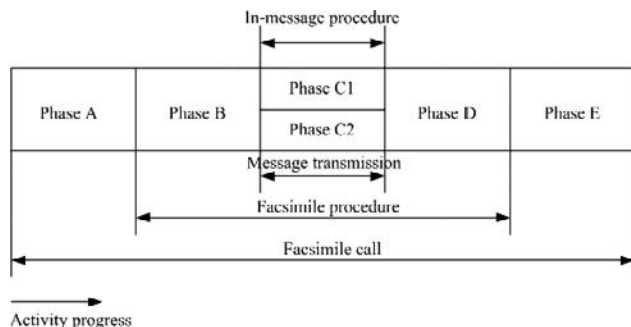

Figure 9: Flowchart of coding procedure

Table 4: Uncompressed Mode Code Words

Entrance code to uncompressed mode	On one-dimensionally coded line: 00000001111 On two-dimensionally coded line: 0000001111

	00001	00001
	00000	000001
Exit from uncompressed mode code	0	0000001T
	00	00000001T
	000	000000001T
	0000	0000000001T
	00000	00000000001T
T Denotes a tag bit which tells the colour of the next run (blank = 1, white = 0)		

Table 5: Eight Transmission Operating Methods

Operating Method	Calling Terminal	Called Terminal	Direction of Facsimile Transmission	
			Calling Terminal to Called Terminal	Called Terminal to Calling Terminal
1	Manual	Manual	1-T	1-R
2	Manual	Automatic	2-T	2-R
3	Automatic	Manual	3-T	3-R
4	Automatic	Automatic	4-T	4-R

**Figure 10:** Sequence of a facsimile

pages are forthcoming, an *end-of-procedure* (EOP) signal is sent, and the called terminal replies with the *message-confirmation* (MCF) signal to indicate that the page has been received successfully. The terminals then proceed to phase E. If more pages are to follow, then a *multipage signal* (MPS) is sent instead of an EOP, and the terminals return to the beginning of phase C. Alternatively, the calling terminal may also send an *end-of-message* (EOM); in this case, the terminals return to the beginning of phase B. If operator intervention is requested, then a *procedural interrupt* (PRI) command (such as PRI-EOP, PRI-MPS, or PRI-EOM) is sent and the terminals return to the beginning of phase B. A complete list of postmessage commands and responses can be found in T.30 (ITU-T 2005).

Phase E: Call Release

The calling facsimile sends a *disconnect* (DCN) signal and both terminals release the call.

All binary-encoded procedural data are transmitted at 300 bits per second ± 0.01 percent using the V.21 channel number two modulation system and encapsulated in HDLC frames for frame labeling, error checking, and acknowledgment of correct reception. All new binary-encoded transmissions are preceded by a preamble that consists of a sequence of HDLC flags (0111 1110) with a duration of 1 second ± 15 percent. This preamble ensures that all elements of the communication channel, such as echo suppressors, are properly conditioned before the transmission of data.

Error Control

The communication channel provided by the telephone network introduces error to digital data transmissions.

The use of an EOL code at the end of each scanned line provides a means for error detection and containment. A number of error conditions may occur:

- EOL occurring before 1728 pels have been decoded,
- more than 1728 pels have been decoded before the occurrence of EOL,
- invalid bit pattern received, and
- in two-dimensional coding, invalid reference to a previous line.

Without EOL, erroneous decoding because of a transmission error may propagate through the entire page. With EOL, transmission errors often lead to annoying streaks in the output page. Before the adoption of the optional error correction mode by ITU-T (Annex A of Recommendation T-4), various error-concealment schemes were used by vendors to minimize the effect of transmission errors. These schemes included:

- all erroneous lines printed white until the first correct MH coded line was received;
- all erroneous lines replaced by the last correctly received line until the next correctly coded line was received; and
- the first erroneous lines replaced by the last correctly received line and all subsequent erroneous lines printed white.

The first erroneous line is decoded and printed normally based on MH or MR up to where the error occurs. After that, the pel from the previous line is printed and also used as reference for the decoding of the next received line in the case of MR.

In the optional error correction mode defined by ITU-T, an HDLC frame structure is used to transmit the coded scan line. A selective *automatic repeat request* (ARQ) scheme is used so that the receiver may request the retransmission of bad frames. The communication channel operates in the half-duplex mode. After four requests for retransmission of the same frame, the transmitter may stop or execute procedures for modem speed fallback.

The error-correction mode provides a basis for other new features such as binary file transfer and operation over ISDN.

Other Enhancements

The *optional file transfer* mode in Annex B of T-4 allows the transfer of any data file with or without additional information. Four file transfer modes are supported:

1. *basic transfer mode* (BTM) for the exchange of files of any kind without any additional information;
2. *document transfer mode* (DTM) for the exchange of files of any kind with a structured file description (file name, file type, file coding, etc.) that may be processed automatically or read by the user at the receiving side;
3. *binary transfer mode* (BFT), which is similar to DTM, with structured file description processed automatically only at the receiving side; and
4. *electronic data interchange for administration commerce and transport* (EDIFACT) transfer, or the exchange of EDIFACT files according to ISO 9735.

The *optional character mode* in Annex C of T-4 supports the reliable transfer of character coded documents by means of the T-30 protocol and the Annex A error-correction mode. The repertoire of graphic characters supported includes those allowed by ISO/IEC 8859-1 and the box-drawing characters repertoire in registered ITU-T set ISO 72. A basic page format of fifty-five lines with seventy-seven characters each is assumed, and control functions are incorporated to act on the formatting of the document and character attributes.

The optional mixed mode in Annex D allows pages with both facsimile-coded and character-coded information to be transferred between terminals. Again, the use of the error-correction mode is mandatory.

Next, we discuss a number of enhancements made to support the transfer of gray-scale and color images. These enhancements include the use of:

- clumped and ordered dithering to create bilevel representation of gray-scale images;

- JPEG as described in Annex E, optional continuous-tone color mode; and
- JBIG as described in Annex G, transmission of color and gray-scale images using lossless coding schemes.

Group 3 was originally designed for bilevel (i.e., black and white) images such as those created by handwriting and line drawings. Gray-scale images are also frequently encountered by a fax machine, so dithering was employed by vendors to achieve better results for such images. Dithering is performed only by the transmitting terminal and is not part of the T-4 standard.

For the case of standard G3 fax, each pel is either a 1 or a 0. If a fixed threshold is used for this single-bit analog-to-digital decision, any gray-scale information in the original will be lost and the resulting digital image may frequently show blocks of black and white areas. With dithering, this threshold is varied either randomly or systematically, so that the gray scale in the original can be reflected by a varying density of black pels in the resulting digital image, a technique used broadly in black-and-white printing (Yasuda et al. 1985; Jarvis, Judice, and Ninke 1976). The mechanism of dithering is illustrated in Figure 11.

In random dithering, the decision threshold is varied randomly. In *clumped dithering* and *ordered dithering*, the decision threshold is varied according to a fixed pattern. Figure 12 shows a clumped dithering scheme in which an

Figure 12: Clumped dithering scheme

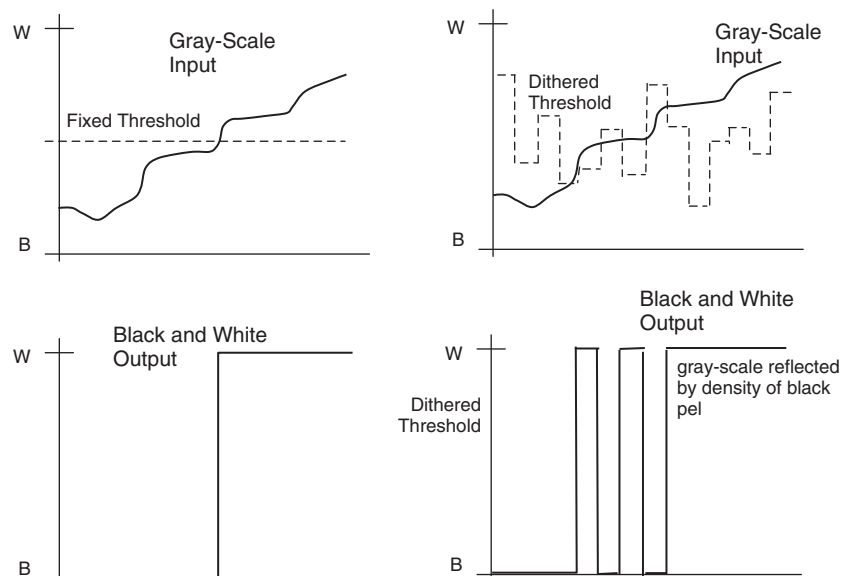

Figure 11: The dithering process

8	136	40	168
200	72	232	104
56	184	24	152
248	120	216	88

Figure 13: Ordered dithering scheme

image is made up of repetitive and interlocked clusters of 17 pels. The decision thresholds, based on 256 brightness levels, are varied in a fixed pattern as we move away from the center of the cluster. This way, regions of different brightness levels in the original image will be represented by clusters of black dots of different density in the bilevel image. This technique is equivalent to the halftone screening process used for printing photos in newspapers.

The idea of ordered dithering is similar to that of clumped dithering. In ordered dithering, the cluster is a square matrix. A 4×4 Bayer-type ordered dither threshold matrix is shown in Figure 13.

The problem in applying dithering to group 3 fax images is that the efficiency of the MH and MR codes is greatly reduced because dithering greatly reduces the run lengths of 1's and 0's.

The use of *JPEG*, the Joint Photographic Experts Group standard for encoding continuous-tone color fax images, was added to the group 3 standard in 1994. This option is described in Recommendation T-42 and Annex E of T-4. *JPEG* specifies two classes of coding processes: *lossy* and *lossless*. The lossy process is based on discrete cosine transform (DCT), and the lossless process is based on predictive coding. Group 3 adopted the (L^* a^* b^*) color space defined by the Commission internationale de l'Eclairage (CIE) in 1976. The three components are L^* for lightness and a^* and b^* for chrominance. T-42 also defined the following different multilevel image-transfer modes:

- *lossy gray-scale mode* (LGM),
- *lossy color mode* (LCM).
- *lossless gray-scale mode* (LLGM), and
- *lossless color mode* (LLCM).

The selection of these modes is accomplished through the DIS and DCS frames described in T-30.

Although *JPEG* is a popular color image coding standard, it suffers from low efficiency when bilevel images, particularly textual and handwriting images, are encoded.

Following T.42, Recommendation T.43 defines a lossless encoding option that is intended for images with textual and line drawing content and limited color information. T.43 uses the color encoding scheme specified in T.82 (JBIG), and defines four types of images:

- one bit per color CMYK* or RGB** images,
- palettized color images,
- continuous-tone color; and
- gray scale.

* Cyan, magenta, yellow, black.

** Red, green, blue.

Different color representation, bit-plane decomposition, and coding methods are defined for these different image types. This option is described in Table 6 (from Annex G of T.4); Table 6 includes T.4's Annex G tables for image mode classification and color and gray-scale mode classification.

The *error correction mode* (ECM) specified in Annex A must be used for data transfer under the *JPEG* option and the *JBIG* option.

Lastly, the *mixed raster content* (MRC) option described in Annex H of T.4 defines a way to efficiently represent raster-oriented pages that contain a mixture of multilevel (e.g., continuous-tone and palettized color) and bilevel (e.g., text and line art) images. Standardized in Recommendation T.44, MRC does not introduce new encodings or resolutions but achieves enhanced efficiency by combining different encoding schemes and different spatial and color resolutions on a single page. It decomposes an image with a three-layer model consisting of the following layers:

- foreground (multilevel, text color),
- mask (bilevel, text shape, and rectangular text and continuous-tone outline)
- background (multilevel, continuous-tone images).

Considering that device memory may be limited in facsimile terminals, MRC provides ways to divide a page into horizontal strips. The maximum strip size is negotiated and may range from 256 lines to the full length of the scanned page. Although the mask layer must span the whole area of a strip, the foreground and background layers may cover only part of the strip. There are also three types of strips, each one depending on the type of data it contains:

- a *three-layer strip* (3LS) contains all three layers (foreground, mask, and background),
- a *two-layer strip* contains either the mask and foreground layers or the mask and background layers, and
- a *one-layer strip* contains only one of the three layers, with the other two set to fixed values.

NEW FACSIMILE SYSTEMS

The Group 4 Standard

The group 4 recommendation is designed for digital networks and makes use of the open system interconnection (OSI) seven-layer model for communications. Groups 3 and 4 facsimiles provide similar performance, and both use a similar set of encoding schemes for images. The main focuses for group 4 facsimile were operation over the then-emerging ISDN and interoperability of facsimile with other messaging systems and services. Under the group 4 standard, a facsimile terminal may bring new capabilities such as:

- interworking with remote computers as an input/output device (e.g., the fax terminal as keyboard, printer, and scanner or the computer as a storage and processing device for optical character recognition) and

Table 6: Image Mode Classification

Image type	Coding sub-mode class	Image specification	Number of bit-planes to be coded
One bit per color image	One bit per color image	One bit per colour image using RGB or CMY(K) primaries	CMY(K) image: 4 bit-planes CMY image: 3 bit-planes RGB image: 3 bit-planes
Palettized color image	Basic palettized color	Palettized image using 12 bits or less entries and 8 bits/comp.precision table	1 to 12 bit-planes (palette-table: up to 4096 entries 2 octets/entry)
	Extended palettized color	Palettized image using 13 to 16 bits entries and 8 bits/comp. precision table or 16 bits or less entries and 12 bits/comp.precision table	13 to 16 bit-planes (palette-table: 4097 to 65536 entries 3 octets/entries) or 1 to 16 bit-planes (palette-table: up to 65636 entries 6 octets/entry)
Continuous-tone image	Colour 8 bits/comp.color 12 bits/comp.color	2–8 bits/comp. 9 to 12 bits/comp.color image	2 x 3–8 x 3 bit-planes 9 x 3–12 x 3 bit-planes
	Gray-scale 8 bits gray-scale 12 bits gray-scale	2–8 bits 9 to 12 bits gray-scale image	2–8 bit-planes 9–12 bit-planes

Table 7: Group 4 Recommendations Used in Conjunction with Recommendation T.6

Recommendation	Subject Covered
T.503	A document application profile for the interchange of group 4 facsimile documents
T.521	Communication application profile for document bulk transfer based on the session service (according to the rules defined in T.62 bis)
T.563	Terminal characteristics for group 4 facsimile apparatus
T.73	Document interchanges protocol for telematic services
T.62	Control procedures for Teletex and group 4 facsimile services
T.62 bis	Control procedures for Teletex and group 4 facsimile services based on Recommendations X.215/X.225
T.70	Network-independent basic transport service for Telematic services
F.161	International group 4 facsimile service

- interworking with the public data network for e-mail and other messaging services.

Under group 4, three classes of fax terminals are defined:

class 1, sending and receiving facsimile documents only at 200 pels/inch;

class 2, scanning, sending, receiving, and printing facsimile documents at 300 pels/inch; and

class 3, having class 2 capabilities plus a keyboard.

The initial image-encoding scheme for group 4 fax is MMR, which is specified in Recommendation T.6. MMR is designed for communication channels with no error or low error rates. In MMR, the starting line is assumed to be a white line, and all lines are encoded as differences from

the line above. EOL is not used, so if an error occurs, all subsequent lines will become invalid until an “all white” or “all black” line is received. T.6 is used in conjunction with the recommendations for group 4 shown in Table 7.

In addition, the following recommendations are also applicable for classes 2 and 3 terminals:

- terminal equipment for use with Teletex (T.60),
- character repertoire and coded-character sets for international Teletex (T.61), and
- terminal capabilities for mixed modes of operation (T.72).

The MMR coding procedure is described by the flow-chart in Figure 14. The code tables used are the same as those in MR.

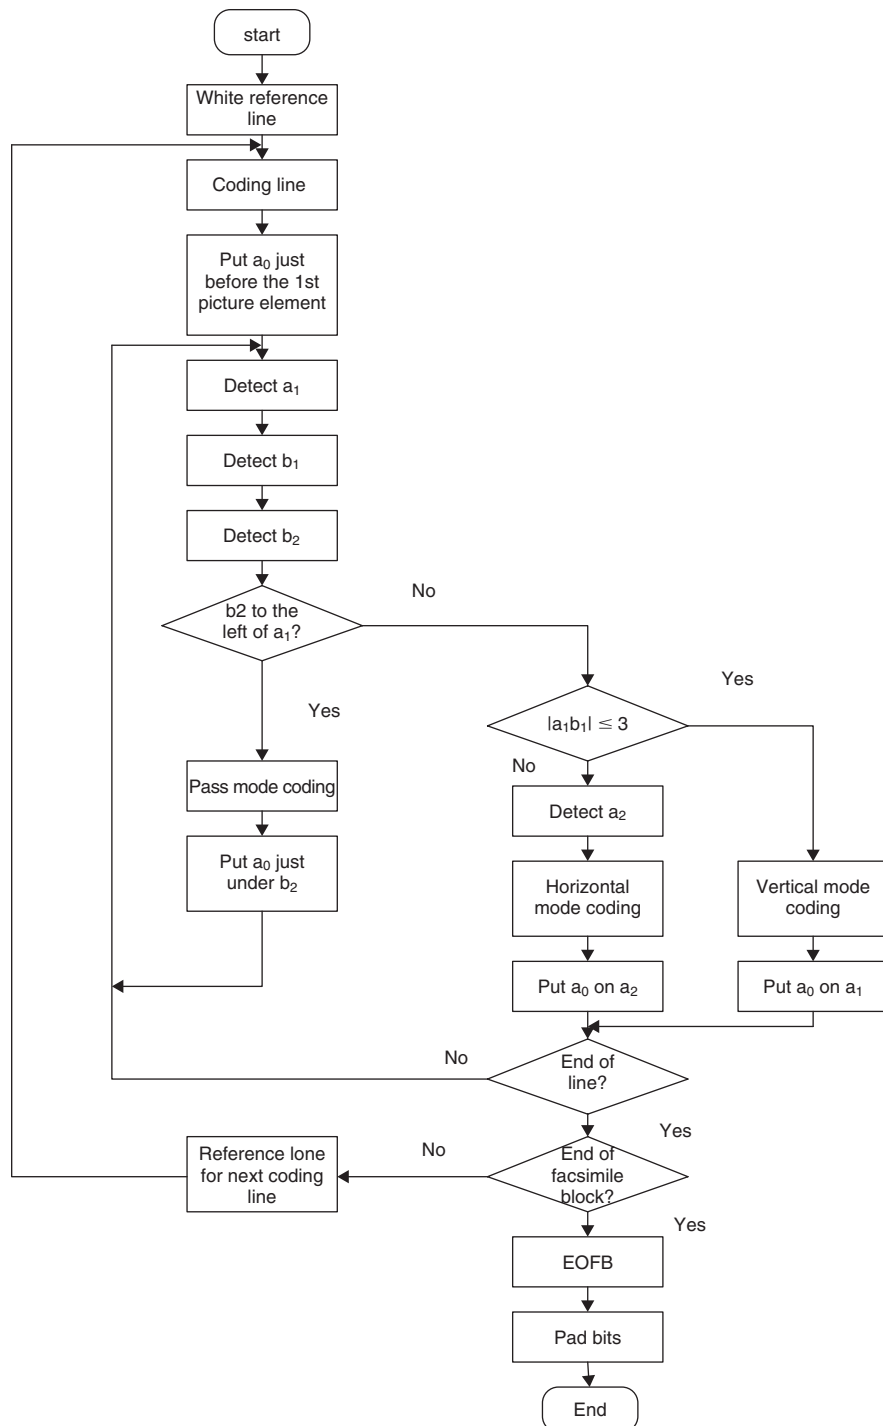

Figure 14: MMR coding procedure. Source: ITU-T Recommendation T.4 (2003).

Internet-Based Systems

The transmission of facsimiles over packet networks was considered before the emergence of the Internet. ITU-T's 1992 recommendations X.5, X.38, and X.39 provided a set of standards for the transmission of facsimiles over the X.25 packet network in a so-called real time mode: where end-to-end negotiations take place between transmitting and receiving terminals so that all standard and

common nonstandard facsimile features and options can be retained to the highest degree possible.

The use of X.25-based fax requires the transmitting terminal to connect to a *facsimile packet assembly and disassembly* (FPAD) device through the PSTN. The originating FPAD determines and makes connection to the terminating FPAD through the X.25 network, and the terminating FPAD makes connection to the receiving fax

terminal through the PSTN. The connection to the originating FPAD can be *manual*, resulting in two-stage dialing by the user; or *automatic* so that the use of the FPAD and packet network becomes transparent to the user.

A second type of facsimile transmission over packet networks is the *store-and-forward service*, which is designed to operate over messaging systems such as X.400 and precludes the use of real-time negotiation. Store-and-forward fax is described in ITU-T's F.162 and F.163. Instead of the FPAD in X.25 facsimile, the *store-and-forward unit* (SFU) is used. Access to the SFU follows a two-stage procedure that is similar to the FPAD access procedure. Notification of delivery failure to the sender is required, but notification of success is optional. Delivery information may indicate delivery to the SFU (level 1), or delivery to the receiving terminal (level 2). The lack of real-time negotiation means that the SFU may need to be sent re-encoded high-resolution pages if the receiving fax terminal is capable only of receiving at a lower resolution. The SFU may also be capable of storing address lists such that a single fax message can be delivered to multiple recipients.

With the emergence of the Internet in the 1990s, the focus of facsimile over packet networks shifted. Standardization work began for facsimile service for which, in addition to the PSTN or ISDN, a portion of the transmission path may be an IP network (e.g., the Internet) (see Figure 15). This scenario is known as *fax over packet* or *fax over IP* (FoIP). A set of objectives for FoIP were drafted by ITU-T Study Group 8 in early 1997 that stipulated that FoIP standards should cover two basic scenarios:

1. Fax terminals can be *Internet-aware fax* (IAF) devices directly connected to the Internet or traditional fax terminals connected to gateways through PSTN or ISDN.
2. Service can be in real-time or store-and-forward mode. In real-time mode, the terminals negotiate and receive acknowledgments during the fax transmission (similar to traditional facsimile). In store-and-forward mode, facsimile data can be stored and delayed before delivery (similar to e-mail service).

The first recommendation from the study group was 1988's Draft Recommendation F.185 (ITU-T 1988), which

described guidelines applicable to the support of both groups 3 and 4 over the Internet (with much left for further study for group 4) and covered both the real-time and store-and-forward modes. The real-time mode for group 3 fax was further standardized in ITU-T Recommendation T.38, which was approved in September 2005. The store-and-forward mode was further standardized in ITU-T Recommendation T.37, which has yet to be approved. In T.37, two modes of operation—*simple mode* and *full mode*—are defined. The simple mode means that capabilities exchange and receipt confirmation are not required but may be provided using optional e-mail functions outside the scope of the recommendation. The full mode means that capabilities exchange and confirmation are required. Simple mode operation is specified in T.37, whereas full mode operation is for further study. T.37 is based on the use of Internet e-mail.

As described in T.38, in real-time Internet facsimile, the contents and sequence of message exchanges between the transmitting and receiving terminals follow those used in conventional fax over PSTN or ISDN to the highest degree possible. The transmitting terminal receives a confirmation of receipt by the receiving terminal before disconnection, and the call duration is similar to fax over PSTN and ISDN. Consider the standard group 3 terminal in Figure 15. To transmit a fax, the terminal first accesses an emitting gateway through the PSTN following the T.30 standard. The emitting gateway then connects to the receiving gateway using an Internet call establishment and control procedure that can be H.323, *session initiation protocol* (SIP), or H.248. The receiving gateway, in turn, makes a PSTN call to the called group 3 terminal. For real-time FoIP, once the PSTN connection is established on both ends, the two group 3 terminals are linked and all standard T.30 session establishment and capabilities negotiations can be carried out directly between them. The transmitting gateway demodulates the T.30 transmissions from PSTN or ISDN, maps the facsimile data into an octet stream using the *Internet facsimile protocol* (IFP) format, and transmits the data through the IP network to the receiving gateway using either TCP or UDP. A key consideration is that the IP portion of the transmission path should have a reasonably low delay so that the requirements specified in F.185 can be met (ITU-T 1998). Recommendation

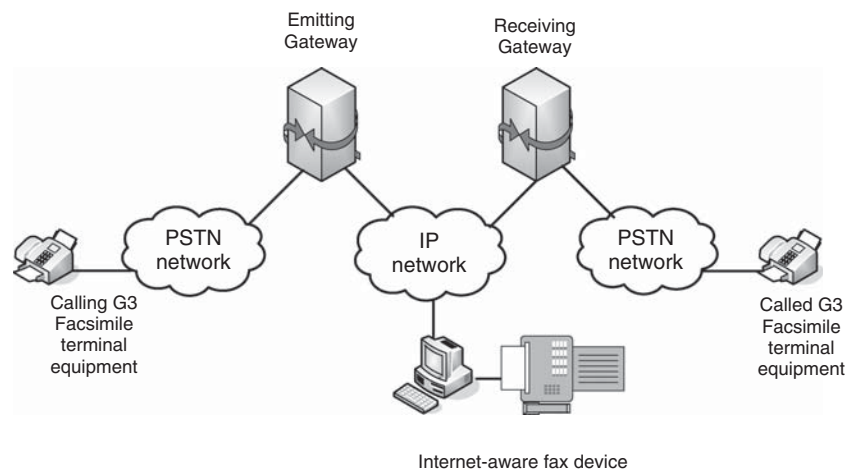

Figure 15: Standard group 3 terminal

T.38 focuses mainly on the operation of devices directly connected to the Internet: the gateways and an IAF device such as a personal computer. T.38 also describes implementation guidelines concerning the preamble packet, intervals between a training packet and an image data packet, and adjustment of T.30 timer values.

The supported call establishment and control protocols—H.323, SIP, and H.248—were originally specified for VoIP. Each of these protocols uses a different architecture and model for call establishment and control. SIP, which was created by the Internet Engineering Task Force (IETF) and is regarded as the most Internet-centric protocol of the three, will be discussed further later in this chapter.

Fax image quality is ensured by error control in the IP network in addition to mechanisms specified in T.30: reliable data transfer via TCP over IP, and higher-layer error control of UDP over IP.

The operation of FoIP may depend on other supporting functions such as directory services for conversion between PSTN and IP addresses, network hunting and selection, user authentication and billing, and network management (SNMP or others), among other functions. These supporting functions are not addressed in T.38 but are covered to various degrees under the H.323, SIP, and H.248 protocols and frameworks. Standardizing these functions will help implement a network based on third-party management devices, including sharing such devices with other Internet gateways such as Internet telephony and video, remote access, and e-mail.

Note that there is also a serious effort from the Internet community to further develop Internet fax. IETF's Internet Fax Working Group has been active since 1996. Documents generated by this group are important references and can be found on the group's Web site (www.imc.org/ietf-fax/). Request for Comment (RFC) 2542, for example, provides the terminology and goals for Internet fax. RFC 2880 describes how to map T.30 group 3 fax into Internet fax. RFC 2301 describes the *tagged image file format* (TIFF) representation of image data for black-and-white and color facsimiles.

As discussed earlier, the simple mode of store-and-forward Internet fax was specified in ITU-T Recommendation T.37. It was based on Internet e-mail, and T.37 draws heavily on relevant IETF protocols for e-mail transport and retrieval—*simple mail transfer protocol* (SMTP), *extended simple mail transfer protocol* (ESMTP), *post office protocol 3* (POP3), and *Internet messaging access protocol 4* (IMAP4)—and on various RFCs for multipurpose Internet mail extensions (MIME). T.37 defines an *offramp gateway* as equipment capable of receiving e-mail and relaying it to one or more group 3 or 4 fax terminals, and a *mailstore* as equipment that is capable of receiving e-mail and storing it for later retrieval by a receiver (see Table 8).

VOICE PROCESSING

Historic Perspectives and Types of Voice Processing Application

Because voice is the most common way for people to communicate, most technologies in the telecommunications

industry have been developed for voice processing ever since the telephone was invented by Bell in 1876. Voice processing is currently a significant part of the industry.

Voice processing involves a variety of technologies that can be categorized into two main areas: call directing and message manipulation (Tetschner 1993). This part of the chapter will focus on these two areas. As time goes on, increasing numbers of voice-processing applications will be developed such as *voice recognition* and *voice over IP* (VoIP). Among the essential tools of voice processing are automatic call distribution, auto attendant features, interactive voice response, and voice message systems.

CALL DIRECTING APPLICATIONS

Automatic Call Distribution

Automatic call distribution (ACD) was originally an application that could distribute incoming calls to a free agent under a previously configured rule that was both inflexible and uneven (Nuasis 2006). Recently, with the ACD being implemented in more and more areas, lots of other parameters have been added to the system, which makes it an increasingly effective telecommunication tool that can evenly distribute incoming calls to a group of people.

ACD is usually used in customer service centers where there are high volumes of incoming calls. Generally speaking, ACD is a load-balancing system that can spread incoming calls to different agents evenly. The rules of distribution in various situations are different from one another, but there are some basic rules: *time of day* (TOD) routing, *day of week* (DOW) or *day of year* (DOY) routing, *area code* or *exchange* routing, and *percentage allocation* routing, among others. Under these rules, ACD can set up a smooth and ordered connection between customers and agents. A typical answer flow of ACD is shown in Figure 16.

ACD can be integrated into the company's *private branch exchange* (PBX). In this scenario, incoming calls from customers are delivered directly to the ACD for processing. This PBX architecture is simple and easy to implement, but it has its limitations; it is suitable for companies that have only one customer service center. Another mode—namely, the ACD system—can be used with a telecom center server. An incoming call will be first identified in the telecom center server and then routed to the appropriate ACD through a local exchange network under the rules that each company needs. Multiple ACDs within the company can also set up connections between each other to guarantee that the service is still available even when some ACDs do not work or all agents behind some ACDs are busy. The ACD can automatically route the calls to other ACDs as in the 800 system. But this process is complex and will increase the cost of management.

With the advancement of technologies, the ACD is becoming more and more sophisticated. For example, with the help of number-identifying systems and customer databases, the agent can immediately obtain necessary information when a call comes in. This will help the agent answer customer inquiries more efficiently. Nevertheless, ACD may not be appropriate for all business.

Table 8: T.37 Implementation Requirements for Simple Mode Store-and-Forward Fax

Sender		
Required	Send image data as a single MIME multipage RFC 2301 Profile S file	RFC 2305 §2.2.3
	Provide notice in case of local transmission problems	RFC 2305 §2.3.1
	Provide a return address of an Internet e-mail receiver that is MIME compliant	RFC 2049
Strongly recommended	Include message ID	RFC 2305 §2.2.1
	Use Base 64 encoding for image data	
Optional	Use other TIFF profiles if it has prior knowledge that such profiles are supported by the receiver (e.g., RFC 2301 Profile F for G4)	RFC 2305 §4
	Provide notice on receipt of DSN or other notifications	RFC 1894
Receiver		
Required	Be MIME compliant except that it is not required to offer to place a MIME attachment in a file and it may print a received file rather than display	RFC 2305 §2.2.2
	Be capable of processing multiple MIME RFC 2301 Profile S image files within a single message	RFC 2305 §2.2.4
	Provide notice in case of reception or processing problems	RFC 2305 §2.3.2
Optional	Use other TIFF profiles (e.g., RFC 2301 Profile F for G4)	RFC 2305 §4
Offramp gateway (when implemented)		
Required	Be SMTP compliant	RFC 821
	Provide delivery failure notification	RFC 1894, RFC 2305 §2.3.1
	Be able to process PSTN/FAX e-mail addresses	RFC 2303, RFC 2304
	Comply with relevant ITU recommendations relating to facsimile transmission	T.30
	Attempt to relay authorized e-mail to the corresponding facsimile terminals G3	RFC 2305 §3.2
	Ensure that local legal requirements relating to facsimile transmissions are met	
Strongly recommended	Use DSN for delivery failure notification	RFC 2305 §2.3.1, RFC 1894
	Use an approved mailbox access protocol when serving multiple users	RFC 2305 §2.1.3
Optional	Translate image data into a format acceptable by the receiving G3 facsimile terminal	RFC 2305 §2.1.2
	Use a mailbox access protocol when serving a single mail recipient	RFC 2305 §2.1.3
Mailstore (when implemented)		
Required	Be SMTP compliant	RFC 821
	Provide delivery failure notification in the form of a DSN	RFC 1894

Source: ITU-T Recommendation T.37, Table 1.1.

Auto Attendant

Today's business relies on voice processing, and customers of such businesses expect voice-processing systems to perform around the clock and have the flexibility to provide all of the functionalities they need. Although an ACD system can provide access to hundreds of agents, it is still not a good tool for the modern business because it gives customers no choice except waiting to be accessed. Nobody will feel satisfied by hearing "All agents are busy now. Please hold on for X minutes!" In this case, other tools to manage the networks are needed.

An *auto attendant* (AA) system allows callers to be automatically transferred to an intended extension without a receptionist's intervention. A receptionist, who acts as the telephone operator, can be reached by pressing "0" on most systems. An auto attendant is a feature on most modern PBX and key telephone systems (Tetschner 1993).

Auto attendant (AA) phone systems can be fully configured and customized to meet the company's need to answer all incoming calls. Figure 17 shows an AA system's basic answer flow.

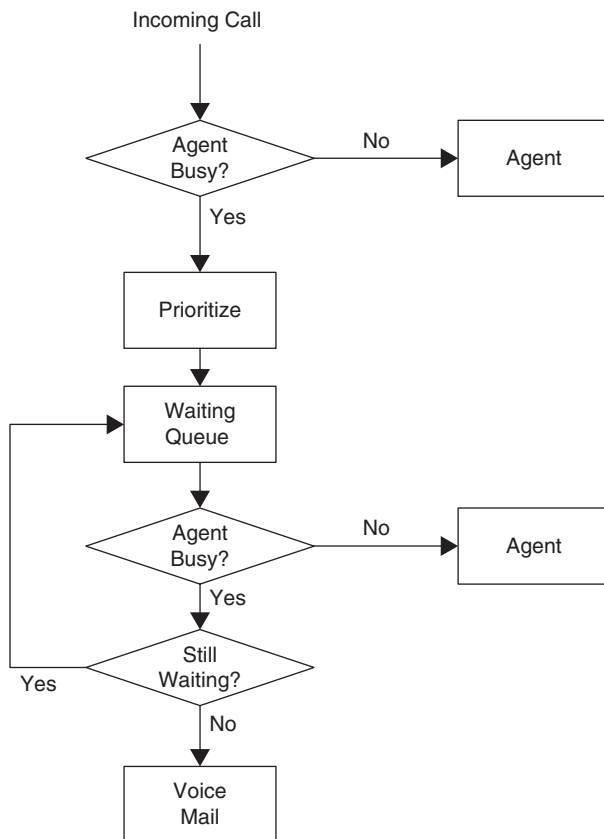

Figure 16: Typical ACD answer flow

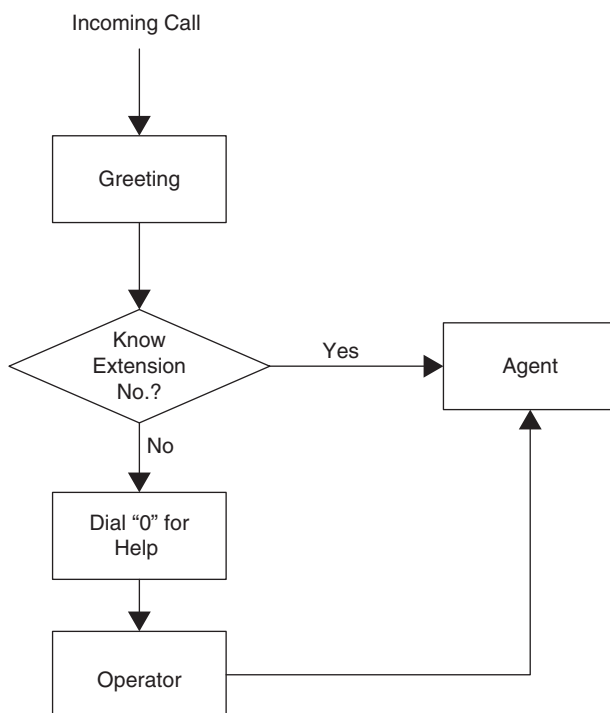

Figure 17: Answer flow of an auto attendant

The AA is designed to take responsibility for answering *frequently asked questions* (FAQs) away from human agents, who can save their time and serve customers who really need assistance. It can also help companies reduce the cost of management.

The AA usually has the following functions: answering the telephone, announcing options to a caller, accepting input from a caller, and forwarding the call to a human agent if no options are chosen.

Interactive Voice Response

Neither ACD nor AA systems can entirely replace the human agent. Although ACD and AA can improve the efficiency of the system, answer FAQs, and balance loads, final answers or information must still come from human agents, so we need a system with more intelligence.

Interactive voice response system (IVRS) is one such system. The IVRS is an automated telephony system that interacts with callers, gathers information, and routes calls to appropriate recipients. An IVRS accepts a combination of voice telephone input and touch-tone keypad selection, and provides appropriate responses in the form of voice, fax, callback, e-mail, and other possible media. It allows callers to select an option from a voice menu or from an interface within this system. In recent years, the latest IVRSs accept not only the keypad but also natural language speech as input (Bates and Gregory 2001).

As discussed above, the auto attendant can also give callers information, but an IVRS is different. Normally, the data retrieved from an IVRS is stored in other systems such as databases. The IVRS provides an interface between a caller and those other systems where the caller's information is stored. For example, a caller can access his or her bank account through an IVRS.

In most cases, the IVRS should incorporate computers. Figure 18 shows the basic architecture an IVRS. An IVRS can reduce the number of human agents but not eliminate the need for them. When a caller needs to speak to a customer service agent, the call still needs to be redirected to an ACD for queuing.

Outbound Dialers

In the modern business market, just waiting for customers' calls may be not enough. Many companies need a technology that will automatically help them reach potential customers.

Predictive dialers, which were developed from auto-dialers, are the technology these companies need. A predictive dialer is a computerized system that automatically dials batches of telephone numbers for connection to agents assigned to sales or other campaigns. A predictive dialer not only automatically dials telephone numbers for call agents who are free but also uses a variety of statistical algorithms to predict both the availability of agents and called parties, and then directs the calling process to the appropriate agents. Predictive dialers are widely used in call centers. They discard unanswered calls, engaged numbers, disconnected lines, answers from fax machines, answering machines, and similar automated services, and only connect agents with calls answered by people.

Figure 18: Architecture of an IVRS

There are two types of predictive dialer: the *software dialer* and the *hardware dialer*. The operating principles of both types are the same, but the software dialer is cheaper while the hardware dialer can provide more function.

A *progressive dialer* is another type of outbound dialer. It will automatically dial numbers for a human agent, but the agent must take action on each call to handle the request from customers. Apparently, it is not as efficient as the predictive dialer (see Table 9).

In some cases, outbound system need to be mixed with inbound systems—for example, with *blended dialing*. In blended dialing, whenever a new outbound record is requested, the phone is first put into the ACD queue. If an inbound phone call is received, it will be processed instead of the outbound record.

Voice Messaging

With the help of ACD, AA, and IVR, a company now may need fewer human agents but cannot totally eliminate

the need for them. For those companies with small numbers of people, there might be times when everyone is engaged. For such small companies, they need another technology called a *voice messaging* (VM) system.

The VM system, invented by Gordon Matthews, is a centralized system of managing telephone messages for a large group of people. VM uses a centralized server rather than an answer machine at each individual telephone. Most VM systems also have the ability to forward messages to another voice mailbox, send messages to multiple voice mailboxes, add voice notes to a message, store messages for future delivery, make calls to a telephone or paging service when a message is received, transfer callers to another phone for personal assistance, and play different message greetings to different callers (Bates and Gregory 2001).

Sometimes, VM systems can be integrated with the AA system to give callers more choices.

Table 9: Progressive Dialing versus Predictive Dialing

	Progressive	Predictive	Predictive
		30 agents	70 agents
Abandonment (%)		1	5
Time talking (%)	53	70	7
Talk time per hour (min.)	31:48	41:59	45:27

Figure 19: Typical voice messaging system architecture

ARCHITECTURE AND EXAMPLE SYSTEMS

Figure 19 shows a typical voice messaging system architecture. With this architecture, the voicemail system usually allows the following functions:

- message dictation to the system;
- message delivery to the called party;
- indication to called parties that they have new messages;
- stored messages can be listened to, forwarded, or deleted by the called people; and
- the attribute of the voice mailbox can be modified by users.

A typical VM system is the one provided by a mobile phone operator. When the called party does not answer the phone, the calling party will be redirected to the VM system and invited to record a short voice message. The VM system will provide some indication of a missed call voice message to the called party by a *short message service* (SMS). The called party then calls his or her mailbox in the VM system to retrieve the message and can then decide to store, forward, or delete the message.

Implementing a VM system requires careful consideration. For example, the allowed length of a message should be calculated carefully; the length will depend on where and how the voicemail will be stored. In addition, not everyone likes to talk to a machine, so the VM system should be integrated with other technologies such as ACD, AA, and IVR.

Audio Messaging Interchange Specification

In today's business world, voicemail boasts an installed base of more than 10 million mailboxes and 500,000 systems (Daniels and Goh 1998). Most major suppliers of voicemail systems provide their own standards for delivering voice messages between their systems. However, interworking among different systems may become a problem for some customers.

The *audio messaging interchange specification* (AMIS) is a series of standards aimed at addressing the problem

of how voice-messaging systems produced by different vendors can be networked and interact with each other (AMIS Group 1992). The AMIS contains two specifications: *AMIS-analog specification* (AMIS-A) and *AMIS-digital specification* (AMIS-D), the latter based on completely digital interaction between two voice-messaging systems. The definitions for the two specifications are given as follows.

The AMIS-A method relies on telephone channels for connection, using *dual-tone, multifrequency* (DTMF) signaling and message transmission in analog form (AMIS Group 1992). AMIS-D, on the other hand, is based on the International Telecommunication Union (ITU)'s X.400 series of messaging recommendations. All of the control information and the voice message itself is conveyed between systems in digital form (AMIS Group, 1993).

AMIS-Analog

AMIS-A provides a mechanism for transferring voice messages among voicemail systems with similar functions but different architectures and technologies. It provides defined formats for identifying message origins and destinations, addressing messages, and sending, receiving, and replying to messages.

AMIS-A provides an open access networking, which means that when two voicemail systems support AMIS-A, the users within these two systems can send messages to each other without any problems. AMIS-A systems are designed to be used on the PSTN, accessing the telephone network via dialup ports that are addressed using *international direct dialing* (IDD) telephone numbers (and direct distance dialing for calls within country) (AMIS Group 1992). An IDD number contains a country code, area code, and local telephone number.

AMIS-A meets the needs of small system users and vendors. Because small systems have low traffic volumes, setting up a new network such as a completely digital one is therefore not necessary. Because of the use of analog DTMF control signaling and analog audio message transmission, AMIS-A can be implemented in the existing network without adding networking equipment.

AMIS-A is designed for simple implementation. It only supports the most common functions of different VM systems such as sending, receiving, and replying to

Table 10: AMIS Digital Stack

Layer Number	Layer Name	AMIS Digital Recommendations
7	Application	MHS X.400
6	Presentation	X.409
5	Session	X.225 BAS
4	Transport	X.224
3	Network	X.25 Packet
2	Data Link	X.25 LAPB
1	Physical	V.32 or V.35

Source: AMIS Group 1993.

messages. It does not require password exchange, and all addressing information required for call setup, message delivery, and message reply can be provided by the voice-messaging subscriber. Furthermore, AMIS-A is designed such that no significant changes are required for user interfaces at terminal devices. Messages transmitted using AMIS-A should be transposable to and from existing system formats.

As discussed above, AMIS-A also specifies a maximum message length and a maximum number of messages that may be delivered per session, a consideration of the storage capacity limits of the typical AMIS-A system. In addition, these limits help avoid situations in which one party occupies the system for overly long periods of time. The AMIS-A protocol enforces these limits by providing a mechanism for the destination system to reject messages that exceed the length limit and to terminate sessions when the message limit is exceeded (AMIS Group 1993).

The disadvantage of AMIS-A is that it does not support extended features such as message receipt notification, importance, or privacy. To achieve parity between different voice-messaging systems, the specification was depressed to a point where the technology no longer provided the robust, full-featured functionality desired by customers (Candell 2004). Fundamentally, customers had to give up some functions in order to gain the ability to communicate with other users in different systems. This compromise did not meet the needs of the market, and vendors scrambled to find an alternative solution that could take advantage of the full features of their messaging system and thus give themselves a competitive advantage in the marketplace (Rabiner 1994). The AMIS-digital protocol described following can provide full function and more complex networking capabilities for customers.

AMIS-Digital

Two alternative protocol stacks are supported in AMIS-digital. One stack—X.25—is in strict accordance with the seven-layer *open systems interconnection* (OSI) model of the International Standards Organization (ISO) (AMIS Group 1993). The other protocol stack matches the X.25 stack in the upper layers but replaces it with TCP/IP in the lower layer. This protocol stack is thus called the

TCP/IP stack. Both alternatives provide an effective base for the X.400 messaging protocol used in AMIS-digital (AMIS Group 1993). The X.25 stack is the baseline for the AMIS-D protocol. The TCP/IP stack on a VM system is optional.

The emphasis of the X.25 stack in AMIS-digital is on circuit-switched transmission facilities. When using the TCP/IP stack, different AMIS-D nodes will be connected by local area network (LAN). All of the LANs can be connected by IP routers to form a whole system. In addition, it is easy to connect VM systems to the Internet by IP routers.

The AMIS-D protocol stack is structured in seven layers (see Table 10). Each layer performs specific functions and provides services to the next higher layer. Implementation at each level can be developed separately (AMIS Group 1993).

A store-and-forward mode is used in an AMIS-D VM system. This concept is realized in the AMIS-digital protocol by separating the message-transfer functions from the user-to-user functions. This allows delivery to an intermediate message relay node without requiring delivery to a user, thereby providing the functionality of a tandem node (AMIS Group 1993). In this way, the topology will be more efficient. It will concentrate traffic through certain nodes to better utilize high-bandwidth digital services for those VM systems with lower volume messages. Sometimes, the store-and-forward topology can also act as a gateway between two protocols—for example, between AMIS-D and AMIS-A. For the X.25 stack only, another mode can be used. It assumes that a direct connection (switched or nonswitched) will exist to transport messages between sending and receiving systems. This model is, in fact, a subset of the store-and-forward model (AMIS Group 1993).

A message transmitted by an AMIS-D VM system can have some attributes that will be visible to both message senders and receivers. These message attributes are maximum length, maximum number of addresses, privacy, sending priority, importance, and sending time stamp.

The maximum length for an AMIS-D messages is eight minutes. The maximum number of addresses for a single AMIS-D message is 128. A message can be marked

by its sender to be “private,” which means that it is not allowed to be forwarded or redirected by any recipient. But if the receiving system does not support this feature, the message will be rejected. A sending system may allow any of as many as three transmitting priorities for a message: urgent, normal, and low. A sending system can also mark one of three importance levels to a message: high, normal, and low. Finally, the message-sending time stamp means that each message transmitted in AMIS-D VM systems be tagged with the date and time when it is sent by its originator.

Message senders can receive one of several kinds of notification upon message delivery:

- nondelivery notification (NDN),
- delivery notification (DN),
- nonreceipt notification (NRN),
- receipt notification (RN), and
- service notification (SN).

As discussed above, the main advantage of AMIS-D is that it can provide more features than AMIS-A. Table 11 shows the differences between these two VM systems.

Computer Telephony Integration and Unified Messaging

In fact, computers have already appeared in the systems discussed above. For example, with the help of computers, agents can access customers’ names, addresses, and telephone numbers before a call is distributed by an ACD system. The voice traffic can also be encoded into a digital format and stored on the hard disk of computer as a database.

Standards

Computer telephony integration (CTI) is the technology that allows coordinated interactions between telephones and computers. As contact channels have expanded from voice to data and now include e-mail, Web, and fax, CTI has expanded to integrate all customer contact channels (voice, e-mail, Web, fax, etc.) with computer systems (Asatani 1998).

CTI can have several basic functions such as calling party information display, on-screen dialing, on-screen phone control, coordinated phone and data transfers between two parties, and call center phone control. Some other advanced functions such as call routing can be provided by a CTI system.

There are two modes of CTI, namely, *first-party control* and *third-party control*. For the first mode, only the computer associated with the phone can control the phone by sending commands directly to it. In the second mode, a dedicated telephony server that connects the telephone network and the computer network is required. The user’s computer has no direct connection to the telephones; the action is actually conducted by the dedicated telephony server. Information about a phone call can display on the corresponding computer’s screen while commands to control the phone can be sent from the computer to the telephony server.

An effective CTI can significantly reduce the cost and improve the quality of data handling in the telephony system.

Unified Messaging

Unified messaging (UM) is the integration of different streams of messages such as e-mail, fax, voice, and video into a single mailbox that is accessible from a variety of

Table 11: Comparison of AMIS-D and AMIS-A Protocols

Feature	Digital	Analog
Send	Yes	Yes
Receive	Yes	Yes
Reply	Yes	Yes
Notification of nondelivery	Yes	Yes
Delivery notification	Yes	No
Forward	Yes	No
Full duplex message flow	Yes	No
Message importance indicator	Yes	No
Message privacy	Yes	No
Message sending priority	Yes	No
Nonreceipt notification	Yes	No
Originating message time stamp	Yes	No
Receipt notification	Yes	No
Separate originator’s voice name	Yes	No
Service notification	Yes	No

devices (Arbanowski and van der Meer 1999). It is a technology that can replace simple voicemail. UM systems were expected to take advantage of the ubiquity of computers, personal digital assistants (PDAs), smartphones, and 3G networks.

As more and more messaging systems are used in daily life, some people need to receive message notifications no matter when and where, while others do not want to be interrupted by uncontrolled messages. As a result, people are unsatisfied when they manage and keep track of their message on multiple devices and systems, for example, voice mail on PBXs, voice mail on PSTN, mobile phones, fax, e-mail, and instant messaging. Consequently, the UM system is viewed as a better choice as a personal agent.

A unified messaging system provides the ability to reach people almost anywhere and anytime and with the flexibility of allowing people to program and decide when the notifications should be delivered. With the help of unified messaging, customers can reduce the number of mailboxes that they must check for incoming voice, fax, and e-mail messages. They can access all their messages from one interface. On the other hand, service providers and network operators can also benefit from UM. They only need to manage a single UM system rather than multiple message system.

Several vendors and service providers can provide UM solutions, including Cisco, Alcatel, Nortel, Microsoft, and Siemens. Figure 20 shows the basic model of a UM system from Cisco.

The main new network element in the design of a unified message system is the *universal message store*, which is under the control of a unified message system server (Sinnreich and Johnston 2001). The unified message and store can be implemented in various ways by existing protocols such as SIP, XML, HTTP, SMTP, and *real-time streaming protocol* (RTSP). Figure 21 illustrates an

example of unified messaging by SIP, which will be discussed in the next section.

If the called party does not answer the phone, then the UM server will store the caller's voice message. The notification method depends on a user's settings.

The Session Initiation Protocol (SIP) and the Component Server Architecture for Unified Messaging

Session initiation protocol (SIP) is an Internet application-layer protocol intended for the control of multimedia communication sessions: the establishment, modification, and termination of multimedia calls over the Internet. SIP was developed by the IETF's Multiparty Multimedia Session Control (MMUSIC) Working Group, with work starting in the mid-1990s and reaching maturity in 2002. Modeled after the hypertext transfer and simple mail transfer protocols, SIP is hailed as the third application-layer protocol of the Internet, and the Internet application layer protocol that will herald in the age of multimedia communications over the Internet. In November 2000, SIP was accepted as the signaling protocol for the *IP multimedia subsystem* (IMS), which was defined by the Third-Generation Partnership Project (3GPP) as the core network of the future to support mobile as well as fixed-line voice and multimedia communications. Since then, SIP has been recognized as the leading signaling protocol for VoIP. SIP represents also the apex manifestation of the client-server model prevalent in the Internet until the emergence of the peer-to-peer model in the early 2000s. In this section, we will describe how SIP and the component server architecture provide the vision of a flexible and dynamic model for the support of converged unified communications.

Figure 20: Unified messaging model.
Source: www.cisco.com 2002

Figure 21: Figure 18 Unified messaging by SIP

In the previous section we described the notion of unified messaging. Unified communications (UC) can be viewed as UM with the addition of call control to integrate real-time sessions with messaging. Converged unified communications means the support of UC over a common network: the Internet.

SIP Characteristics

The following is a description of the characteristics of SIP:

First, SIP is a text-based Internet application-layer protocol that uses a request-response model. There are header lines in the request and a response code in the response. All of these are similar to HTTP and SMTP.

Second, SIP uses the *uniform resource indicator* (URI) for addressing. URI is a generalization of the *uniform resource locator* (URL) used for e-mail and Web addresses. Like e-mail and the Web, SIP uses the *domain name system* (DNS) to convert e-mail-like destination address of “users” to the network address of “servers” that serve the users. SIP may make use of other directory systems such as ENUM, which will enable SIP to handle addresses in the form of E.164 telephone numbers. The analogy with e-mail makes obvious SIP’s global scalability and mobility. Although it takes a telephone company expensive equipment and software and significant deployment time to provide telephony services to a new community, it takes no more than a couple of hours to set up an e-mail server and allow everyone in a new company or department to enjoy sending and receiving e-mails to and from anyone around the world. Whereas a fixed line telephone number is tied to a fixed location and a mobile telephone number is tied to a mobile phone (or SIM card), an e-mail address is independent of location and device. A user can be behind any device in any location while retrieving his or her e-mails.

Third, SIP makes use of *session description protocol* (SDP), which was originally designed to support the description of multicast sessions over the Internet, to describe how the end systems would like to communicate with each other (IP address, port number, codec types,

bit rates, and so on). SIP provides the carrier service for the SDP message.

Fourth, SIP follows the “smart client, dumb network” paradigm of the Internet. SIP and the IP network provide the mechanism for the *rendezvous* function—that is, “finding” and connecting to the destination—while the service logics are implemented in the end systems. It is up to the end systems to decide how to process an incoming call request. Many conventional PBX and PSTN call features—such as call hold, transfer, call forward, call screening, and call waiting—can be easily implemented with call logics in the call server or in the end systems. New services can be provided by additional servers (service controller, presence server, databases, IVR, UM store, voicemail, text-to-speech converter, media mixers, event schedulers, and so on) based on what is known as the component server architecture paradigm. Services can also be created dynamically through the use of *call processing language* (CPL) in XML scripts, *SIP common gateway interface* (CGI) similar to the CGI for Web servers, or SIP Java servlets. The mix-and-match of new servers, dynamic service logic, and easy integration of SIP with other Internet protocols make SIP and the component server architecture the key model for service creation and orchestration over the Internet.

Fifth, SIP supports a variety of request types known as *SIP methods*. Five request types are described here to illustrate SIP’s capability: INVITE, REGISTER, SUBSCRIBE, NOTIFY, and MESSAGE. A SIP INVITE request contains an SDP that informs the called party the intention of a communication session. A REGISTER request allows a user to register its current network address and current status so that the network can locate the user when needed. A SUBSCRIBE request allows a user to express his or her desire to be informed of specified events. A NOTIFY request informs the recipient of an event. A MESSAGE request transports an instant message body that is delivered to the recipient. REGISTER, SUBSCRIBE, NOTIFY, and MESSAGE bring capabilities that are not found in the conventional telephone network.

The first standard version of SIP is version 2.0, which was defined in RFC 2543 in March 1999. As many

Figure 22: Basic SIP servers and the SIP routing trapezoid

shortcomings were identified, SIP version 2 was revised substantially in RFC 3261, which was accepted in June 2002. The basic SIP architecture, which consists of user agents (UAs), outbound and inbound proxy servers, a location server, and a registration server, together with the SIP routing trapezoid, is illustrated in Figure 22. User A, who currently sits behind user agent A (a notebook computer), wishes to call user B. On behalf of user A, user agent A generates a SIP INVITE message to user B using B's SIP address, which is *bob@univ456.edu*, and sends this INVITE message to its serving outbound proxy sever. The outbound proxy queries the DNS system to find the inbound proxy server serving the *univ456.edu* domain and then forwards the INVITE to the inbound proxy server. The inbound proxy server then queries its location server, a local database, to find the current network address(es) of user agent(s) serving user B, and forward the INVITE message accordingly.

Note that user B may be using multiple user agents at the same time, and the inbound proxy may opt to fork the INVITE message to multiple destinations. The INVITE message contains the network address of user agent A as a return address, so that the responding user agent B may choose to respond to user agent A directly without the trapezoidal routing. Also, the INVITE message and the response contain SDP bodies specifying the network address, port number, and media type for the communication session. Once the SIP INVITE and response exchange is completed, the media session can flow directly between user agent A and user agent B.

In the component server architecture, servers are added to provide messaging and other services, using SIP as the basic call control and messaging protocol. These other servers may include:

- *UM server* and *UM store* to handle and store messages,
- *media server* to play announcements and other media,

- *IVR server* to provide interactive voice response functions such as touch tone detection and voice recognition,
- *presence server* to keep track of availability and the presence of users,
- *notification server* to accept and fulfill requests for notification of events, and
- *authentication* and *security server* to support security functions.

INTERNET-BASED SYSTEMS AND NEW PROTOCOLS

We conclude this section by mentioning that although there are individual Internet-centric protocols for VoIP and messaging, no other protocol integrates voice and messaging in as comprehensive a manner as SIP. MGCP and MEGACO, for instance, are other popular protocols for VoIP. They do not address messaging. *Extensible messaging and presence protocol* (XMPP), for example, is an open, XML-based protocol for conveying near real-time, extensible instant messaging and presence information. Although it does not address the setup of real-time communication sessions, XMPP is the core protocol for the *jabber instant messaging and presence technology*. Deployed by Google Talk, XMPP is used by millions of people worldwide. IETF's XMPP working group has produced several RFCs: RFC 3920, RFC 3921, RFC 3922, and RFC 3923. It remains to be seen if SIP-based instant messaging system will reach a similar level of popularity.

CONCLUSION

In the first part of this chapter, we began with a review of the history of the development of facsimile, followed

by a detailed description of the group 3 standard which has since its first adoption in 1980 defined the operation of the modern fax machine – for over a quarter century. Our description of the group 3 standard included the coding, specifically the modified READ (MR) code and the modified modified READ (MMR) code, the protocol, and various proposed enhancements. Then we described new facsimile systems including the group 4 standard which was intended for operation over ISDN has not seen wide-spread application, facsimile over X.25, and most recently, internet-based systems which can be real-time or store-and-forward.

Facsimile is a messaging system for images. The second part of this chapter covered messaging for voice. We began with a description of call directing applications including automatic call distribution (ACD), auto attendant (AA), interactive voice response (IVR), outbound dialer, and voice messaging (VM), followed by an overview of the Audio Messaging Interchange Specification (AMIS). Then the concept of computer telephony integration (CTI) and unified messaging (UM) were introduced. We finished the chapter with a description of the session initiation protocol (SIP), mentioned also in the section on internet-based facsimile, as potentially the protocol to unify different call directing and voice/text/image messaging applications in an internet-centric component server-based architecture.

GLOSSARY

- AM:** Amplitude Modulation is a technique used in electronic communication. AM works by varying the strength of the transmitted signal in relation to the information being sent.
- AM-PM VSB:** Mplitude/Phase Modulation with Vestigial Sideband
- BFICC:** British Facsimile International Consultative Committee
- CCD:** Charge-Coupled Device is an analog shift register, enabling analog signals to be transported through successive stages controlled by a clock signal.
- CFVD:** Constant Frequency Variable Dot
- CTI:** Computer Telephony Integration is technology that allows interactions on a telephone and a computer to be integrated or co-ordinated.
- DCS:** Digital command signal
- DCT:** Discrete cosine transform is a Fourier-related transform similar to the discrete Fourier transform (DFT), but using only real numbers.
- DIS:** Digital identification signal
- DSCP:** Differentiated Services Code Point is a field in the header of IP packets for packet classification purposes.
- DTM:** Document Transfer Mode
- DYMF:** Dual tone multi frequency
- ECM:** Error Correction Mode is an optional transmission mode built into Class 1 fax machines or fax modems.
- EIA:** Electronic Industries Association
- FoIP:** Fax-over-IP
- FPAD:** Facsimile Packet Assembly/Disassembly
- HDLC:** High Level Data Link is a bit-oriented synchronous data link layer protocol developed by the International Organization for Standardization (ISO)
- IAF:** “Internet-aware” fax
- IETF:** Internet Engineering Task Force develops and promotes Internet standards, cooperating closely with the W3C and ISO/IEC standard bodies; and dealing in particular with standards of the TCP/IP and Internet protocol suite.
- IMS:** IP Multimedia Subsystem is an architectural framework, originally designed by the wireless standards body 3GPP, for delivering IP multimedia services to end users.
- ITU:** International Telecommunication Union
- IVR:** Interactive Voice Response is a phone technology that allows a computer to detect voice and touch tones using a normal phone call.
- LDP:** Label Distribution Protocol is a protocol in which two Label Switch Routers (LSR) exchange label mapping information.
- LSR:** Label Switching Router is a type of a router located in the middle of a Multiprotocol Label Switching (MPLS) network.
- MH:** is used in fax machines to encode black on white images.
- MIME:** Multipurpose Internet Mail Extensions is an Internet Standard that extends the format of e-mail.
- MPLS:** Multi Protocol Label Switching is a data-carrying mechanism which emulates some properties of a circuit-switched network over a packet-switched network.
- MRC:** Mixed Raster Content is a process of using image segmentation methods to improve the contrast resolution of a raster image composed of pixels.
- NGN:** Next Generation Network is a broad term to describe some key architectural evolutions in telecommunication core and access networks that will be deployed over the next 5–10 years.
- QAM:** Quadrature Amplitude Modulation is a modulation scheme which conveys data by changing (modulating) the amplitude of two carrier waves.
- OSI:** Open Systems Interconnection
- PSK:** Phase Shift Keying is a digital modulation scheme that conveys data by changing, or modulating, the phase of a reference signal.
- READ:** Relative Element Address Designate
- PTT:** Post, Telegraph, and Telephone administrations
- SIMPLE:** Session Initiation Protocol for Instant Messaging and Presence Leveraging Extensions
- SIP:** Session Initiation Protocol is an application-layer control (signaling) protocol for creating, modifying, and terminating sessions with one or more participants.
- SMTP:** Simple Mail Transfer Protocol is the de facto standard for e-mail transmissions across the Internet.
- SNMP:** Signaling Network Management Protocol is used by network management systems to monitor network-attached devices for conditions that warrant administrative attention.
- TCP/IP:** Transmission Control Protocol/Internet Protocol
- XMPP:** Extensible Messaging and Presence Protocol is an open, XML-based protocol for near-real-time, extensible instant messaging (IM) and presence information.

INTRODUCTION

The *public switched telephone network* (PSTN) is an aggregation of circuit-switched networks that is optimized for continuous real-time voice communications. Originally a network of fixed-line analog telephone systems, the PSTN guarantees the *quality of service* (QoS) for voice communications characterized by short session time, continuous channel holding, and narrowband bandwidth requirement.

This chapter focuses on the important PSTN components and the provisioned network services, PSTN-enabling technologies and equipments, and the network's performance and management.

Basic Concepts

This section describes the PSTN network access, components, and provisioned services.

Network Access

PSTN features a sophisticated network infrastructure with various components, thereby providing a rich variety of services. The PSTN network can be partitioned into three segments as shown in Figure 1: the access networks or local loops, the local exchange networks, and the interchanges or gateways that interface with long-distance and other networks.

In PSTN, a communication request originates from *customer premise equipment* (CPE) such as a telephone or fax machine that is connected to the access network. A typical connection request may be from residential customers or from business office users. In the latter case, a *private branch exchange* (PBX) may be used to provide private switched services.

The access network, or the *local loop*, is the bridge between the subscribers and the core network. An access network consists of CPEs, PBXs, and access lines lead to

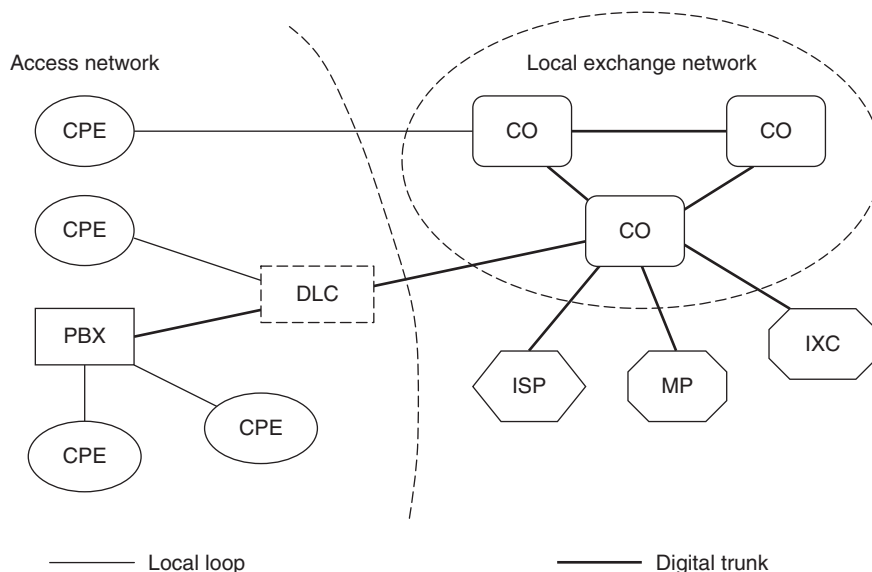

Figure 1: Network access

digital loop carriers (DLCs) or the *local exchanges* (LXCs). DLCs are highly efficient digital transmission systems that reduce the analog line length and economically expand the access network. The access network also includes the logic to control the traffic flow over the access lines.

The core of the PSTN is the local exchange network that interconnects *central offices* (COs). A central office is the physical location where local service providers terminate subscriber lines and locate switching equipments. When it is necessary, connection requests are forwarded by or received from other service providers such as an *interexchange carrier* (IXC) to other local exchange networks, a *mobile provider* (MP) to wireless networks, or an *Internet service provider* (ISP) to the Internet.

Access Services

Access services are categorized into residential subscriber lines and trunks. *Residential subscriber lines* provide connections between residential CPEs and central offices or DLCs.

Trunks are used to provide connections to the PBX. There are three types of trunks: two-way local exchange trunks, direct inward dialing trunks, and direct outward dialing trunks.

Two-way local exchange trunks allow both incoming and outgoing calls. *Direct inward dialing trunks*, also known as DID trunks, are designed for incoming calls only. One benefit of DID trunks is that they allow the caller to dial a number directly rather than go through a centralized attendant. Another benefit of a DID trunk is that although it may appear to be a private line, it is able to support one hundred different numbers with a group of twenty-five to thirty-five trunks. *Direct outward dialing trunks*, also known as DOD trunks, are designed for outgoing calls only. They are used when an access code such as the number 9 is dialed to reach an outside line's dial tone before the actual number is dialed.

Transport Services

Transport services comprise network switching, transmission, and related services that support information transfer between the originating and terminating access facilities. The underlying facilities include local exchanges, tandem switches, toll and transit switches, international gateways, and interoffice transmission equipment. Transport services, which demand the coordination among communication equipments, carriers, and service providers, can be classified into switched services, nonswitched services, and virtual private networks.

There are two types of *switched services*: public and private. *Public switched services* include local calling, long-distance calling, international calling, directory assistance, operator assistance, and emergency services. *Private switched services* can be CPE-based or carrier-based. In case of CPE-based private switched services, the customer can add capabilities to the telephone systems in the PBXs by a feature called *electronic tandem networking*, which can be used to gain flexibility in routing around congestion points. With carrier-based private switched services, a customer can use a *centrex* to partition and implement extensions across multiple local exchanges and to switch

traffic between those locations. The *centrex* is a central office-based telephone service that provides an alternative to PBX. Centrex service includes free calling within the local exchange area, access to long-distance networks, and an abbreviated dialing plan that can be used to dial between any two phones that are in the *centrex*.

Nonswitched services include leased lines, *foreign exchange* (FX) lines, and *off-premises exchanges* (OPX). When connected by leased lines, two locations or two devices are always on, using the same transmission path. FX lines allow customers to make toll calls that appear to be local calls. The OPX setup provides a nice solution: lease a circuit to each off-premise location and tie it in as if it were part of the PBX.

A *virtual private network* (VPN) is a concept that originated from the circuit-switched network environment. A VPN defines a network in which the customer traffic is isolated over shared service provider facilities. The underlying facilities of a VPN include the carrier public network augmented by network control points and service management systems. Traffic on a VPN is routed through the public network as if it were in a facilities-based private network.

Service Providers

PSTN services are offered by the following major types of providers (Goleniewski 2005).

- An *interexchange carrier* (IXC) is the carrier for long-distance and international communications. AT&T (acquired by SBC), MCI (acquired by Verizon), Sprint, and Qwest are the primary IXCs in the United States.
- *Public telecommunications operators* (PTOs) are the incumbent carriers in countries other than the United States.
- *Incumbent local exchange carriers* (ILECs) are the original common carriers that had or still have monopoly rights in the local loop. In the United States, these would be one of four so-called baby Bells: Qwest, SBC, BellSouth, and Verizon.
- *Competitive local exchange carriers* (CLECs), which are competitors of ILECs and products of the Telecommunications Act of 1996.
- *Data competitive local exchange carriers* (DCLECs) are companies that provide data service to end users such as DSL service providers.
- *Ethernet local exchange carriers* (ELECs) provide Ethernet solutions in local loops and metropolitan areas. Among others, *Ethernet passive optical network* (EPON) technology provides a feasible solution that makes this new service possible.
- *Value-added network* (VAN) providers offer pipe connections from one location to another location as well as additional services—such as error detection and correction, and protocol and language conversion—to enable interoperability across the network.

PSTN Architecture

According to their functionalities, facilities in PSTN systems are classified into four categories: customer premise

equipment nodes, switching nodes, transmission nodes, and service nodes.

A *customer premise equipment (CPE)* node interfaces the customer and the access network. Its main function is to transmit and receive customer information as well as exchange control information with the local exchange network. CPE nodes include PBXs, key telephone systems, single-line telephones, and facsimile machines.

Switching nodes interconnect transmission facilities at various locations and route traffic through a network. They set up the circuit connections for a signal path based on the number dialed. Switching nodes include the local exchanges (Freeman 2004), tandem switches that route calls between local exchanges within a city, toll offices that route calls to and from other cities, and international gateways that route calls to and from other countries. Primary network intelligence is contained in the local exchanges and tandem switches. The toll switches provide long-distance switching and network features, and local exchanges provide the local switching and telephony features to which customers subscribe. Figure 2 illustrates the relationship between different telephone exchanges.

Transmission nodes provide communication paths that carry user traffic and network control information between the nodes in a network. They are equipped with *transport media* such as twisted pair wires, coaxial cable, microwave transmitters, satellites, and fiber-optic cabling; and *transport equipment* such as amplifiers, repeaters, multiplexers, *digital cross-connects (DCCs)*, and *digital loop carriers (DLCs)*.

Service nodes handle *signaling*, or the transmission of information to control the setup, holding, charging, and releasing of connections, as well as the transmission of information to control network operations and billing.

PSTN Numbering Plan

The PSTN numbering plan is an important part of call routing. ITU-T E.164 (2005) lays out a framework for PSTN addressing. Each telephone consists of one or more of the following parts.

- The *subscriber number* identifies a subscriber within a local numbering area. A local numbering area is one

in which two subscribers can reach each other using the same dialing procedure. The area can be further divided into two parts: exchange code and local code. An *exchange code* is used to identify an exchange within a numbering area. A *local code* is used to uniquely identify a subscriber within the exchange.

- An *area code* (or *trunk code*) is a digit or string of digits that identifies an area within a country. It is also known as a *city code* in some countries.
- A *country code* is a one- to three-digit number that identifies a country (defined in ITU-T E.163).
- An *international access code* is a prefix that asks the local exchange to route a call to an international gateway.
- A *toll access code* is a prefix for domestic long-distance (toll) calls.
- An optional *network access code* allows access to the external network from a PBX CPE.

Figure 3 shows the general numbering plan for international and domestic calls.

Generally speaking, each country or region has its own numbering plan under the framework of ITU-T E.164. In North America, for example, the North American Numbering Plan Administration (NANPA) regulates numbering in Canada, the United States and its territories, and nations of the Caribbean. The NANPA works with industry consensus forums through the Alliance for Telecommunications Industry Solutions (ATIS) and its Industry Carriers Compatibility Forum (ICCF). ATIS's Industry Numbering Committee (INC) is responsible for the technical definition and use of the North American numbering plan's (NANP's) resources. The NANP specifies some numbers for special services, such as N11 and N00 (where $N = 2 \dots 9$). For a complete coverage of NANP, refer to ATIS (2005, 2006) and Web sites listed at the end of this chapter.

Evolution and Standardization

The earliest telephones required no switching because they were installed on a dedicated-line basis (Deese 1984). It quickly became evident that such a one-on-one arrangement was inefficient to meet growing economic

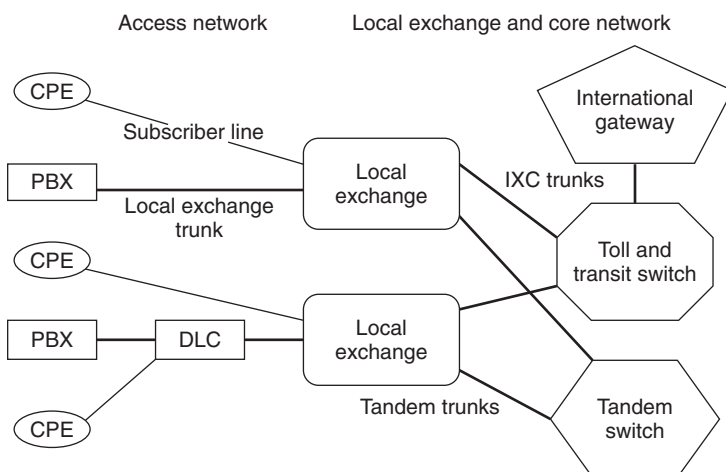

Figure 2: Types of PSTN nodes and their inter-relationships

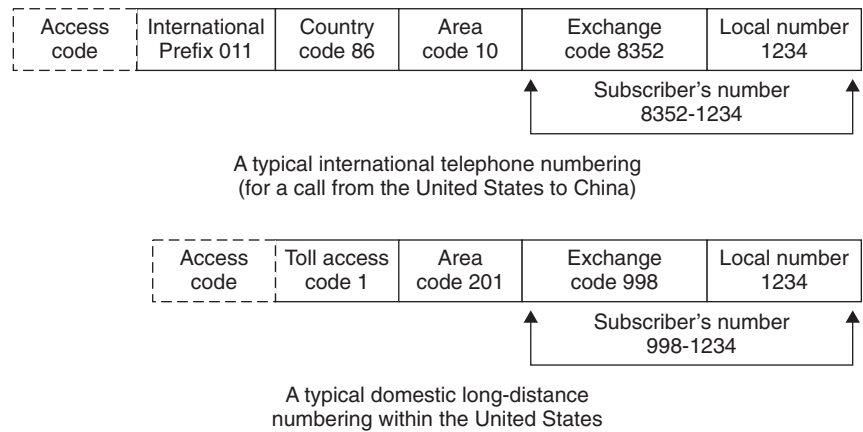

Figure 3: Typical telephone numbering plans (international and domestic) (access code is optional)

and social needs. The newer telephone network began to emerge when telephones were connected to a central location in which an operator could connect and disconnect telephone lines from any pair of subscribers to the service whose lines terminated in that location. In North America, the location was called the *central office*.

To facilitate interconnection, telecommunication equipment must comply with national, regional, or international standards. The most recognized institute of standardization is the International Telecommunication Union (ITU), which has two subsidiary organizations, the Telecommunications Standardization Sector (ITU-T) and the Radiocommunication Sector (ITU-R). Before 1993, ITU-T was called the International Consultative Committee on Telephone and Telegraph (CCITT).

The ITU-T publishes its standardized documents as recommendations. *Synchronous digital hierarchy* (SDH) (ITU-T 2006, G.707) and *signaling system number 7* (SS-7) (ITU-T 1993, Q.700) are two examples of more than 2900 ITU-T recommendations.

In North America, the *American National Standards Institute* (ANSI) is the organization that administers and coordinates the U.S. standardization and conformity assessment system. *Synchronous optical network* (SONET) is one of the thousands of standards approved by ANSI.

PSTN TRANSPORT MECHANISMS

Although the PSTN was created using analog voice connections through manual switchboards, it started to migrate to a digital-based network in the 1980s. Since 1997, North American long-distance networks and local exchange carriers have been nearly 100 percent digital (Freeman 2004).

Digital transmission outperforms analog transmission in three main aspects. First, noise does not accumulate as it does in an analog system. Noise accumulation stops at each regenerative system repeater where digital signals are fully regenerated. Such accumulation is a major concern in analog design. Second, the digital format lends itself ideally to solid-state technology and integrated circuits. Third, such transmission is compatible with digital data, telephone signaling, and computers.

In the following discussions, we will only focus on digital transmission mechanisms and digital networks.

The Digital Transmission System

In this section, we describe the fundamental transmission mechanisms that are essential to digital-based PSTN systems. For a more detailed discussion on digital transmission, readers are referred to “Digital Transmission.”

Pulse Code Modulation

To transmit analog voice traffic over the digital network, voice signals must be converted to a digital format. There are two commonly used conversion methods: *pulse code modulation* (PCM) (ITU-T 1988, G.711), which is used almost exclusively in the digital PSTN, and *delta modulation*, which is widely employed by many of the world’s armed forces. Here we discuss the PCM method.

To develop a PCM signal from an analog signal, three steps are required: sampling, quantization, and coding. The result is a *serial binary signal* or *bit stream*. Figure 4 shows the bit streams in different coding formats for the same analog signal. The *bipolar PCM* mode, also known as *alternate mark inversion* (AMI), is the format actually used in the PSTN network (ITU-T 1998, G-704). In the bipolar PCM mode, the marks—that is, the 1’s—have only 50 percent duty cycle. The advantages of using the bipolar mode are twofold: (1) There is no direct current (DC) in the transmit lines, so transform coupling can be used along the lines; and (2) the power spectrum of the transmitted signal is centered at a frequency equal to one-half the bit rate (Freeman 2004, Sklar 2001).

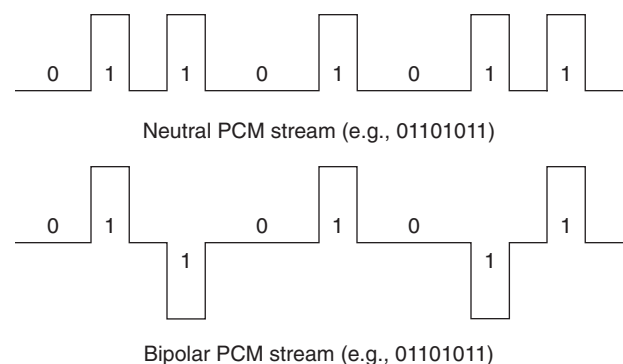

Figure 4: Neutral PCM versus bipolar PCM bit streams

According to the *Nyquist sampling theorem* (Sams 1976), the nominal 4-khz voice channel would be sampled at a rate of 8000 samples per second. The time between two samples is therefore $1/8000$ second = 125 μ sec and is called a *frame*.

After sampling, each sample is quantized and encoded. Modern PCM systems use an 8-bit code to quantize each sample. At the sampling rate of 8000 hz, each voice channel needs to transmit at $8 \times 8000 = 64$ kbps. This signal rate is called the *digital signal zero* (DS-0) rate or E-0, which is the basic rate for all digital transmission systems.

Line Code

As previously discussed, in the PSTN, PCM signals are transmitted to the cable in the bipolar mode, which reduces noise, and eliminates DC return so that transformer coupling can be used on the line. One drawback of the bipolar mode, however, is that when a long string of 0's is transmitted, a timing issue may arise because the repeaters and decoders have no way of extracting timing without transmissions. This issue can be solved by prohibiting long strings of 0's. Two coding systems are available.

One solution is called *BNZS coding* in which the N th 0 of N consecutive 0's are substituted by 1. For example, a B6ZS code substitutes a signal with a string of six 0's. B6ZS is widely used in the subscriber loop carrier.

Another solution is the *high density binary 3* (HDB3) coding system, where 3 indicates the substitution for binary sequences with more than three consecutive 0's. With HDB3, the second and third 0's are transmitted unchanged. The fourth 0 is transmitted to the line with the same polarity as the previous mark sent, which is a violation of the bipolar coding. The first 0 may or may not be modified to ensure the successive violations are of opposite polarity. HDB3 is used in E series PCM systems and is similar to B3ZS.

Frame Format

The frame is an essential concept underlying all digital transmission systems of PSTN. Two frame formats are widely used in PSTN: *digital signal 1* (DS-1) *frame* or *T-1 frame*, and *common European postal telegraphy 1* (CEPT-1) *frame* or *E-1 frame*.

In the DS-1 frame, twenty-four DS-0 channels are each allotted an 8-bit *time slot* (TS)—that is, $125 \mu\text{sec}/24 = 5.2 \mu\text{sec}$. DS-1 time slots are numbered from 1 to 24, or TS1 to TS24. To synchronize the receiver, a frame bit is added to each frame. The DS-1 frame thus consists of $(24 \times 8) + 1 = 193$ bits. At the sampling rate of 8000 hz, the line rate for DS-1 frame is thus $193 \times 8000 = 1,544,000$ bps or 1.544 Mbps. Figure 5 shows the DS-1 frame format.

Figure 5: DS-1 frame format (frame length 193 bits in 125 μ sec)

Higher rates are achievable by multiplexing DS-0 channels and are referred to as *digital signal n* (DS- n), where n can be 2, 3, and so on.

In the DS-1 system, supervisory signaling is “in-band,” with bit 8 of every sixth frame “robbed” for supervisory signaling. Two enhancement schemes are widely used: *superframe* (SF) and *extended superframe* (ESF). A SF is illustrated in Figure 6 (ITU-T 1998, G.704).

An ESF is similar to an SF, with enhancement of signaling and usage of S-bits, as specified in ITU-T G.704 (1998).

In the CEPT-1 or E-1 PCM systems, a frame consists of thirty-two channels (TS0–31), thirty of which are used to carry voice or data; the remaining two channels transmit synchronization alignment (TS0) and signaling information (TS16). Each time slot is $125/32 = 3.906 \mu\text{sec}$. An E-1 frame thus contains $32 \times 8 = 256$ bits, resulting in a line rate of $256 \times 8000 = 2,048,000$ bps or 2.048 Mbps. Table 1 shows the E-1 frame format.

In TS0, a synchronizing code word is transmitted every second frame, occupying digits 2 through 8 as below:

E-1 synchronizing code word: 0011011

In those frames without the synchronizing code word, the second bit of TS0 is set to 1.

The frame format and the digital hierarchy (see the section below) define the PSTN carriers into T, E, and J categories, as described in the next section.

Internetworking between Hierarchies

When two different hierarchies (i.e., the T1- and E1-based systems) internetwork at the boundary between two countries, a time-slot interchange procedure occurs, whereas the *digital cross-connect* (DCC) maps the 8-bit time slots from one hierarchy into the corresponding time slots in the other hierarchy. Although a time slot that carries data patterns will be mapped across unchanged, a time slot that carries voice speech requires the PCM A-law to μ -law conversion, or vice versa, at the internetworking point. Figure 7 depicts the internetworking between the T1- and E1-based hierarchies.

Differences between the T1 and E1 Network and Broadband Integrated Services Digital Network

We introduce this subsection mainly for completeness. Generally speaking, both T1- and E1-based networks and ISDN networks can transmit data and speech traffic. Specifically, the ISDN can run on top of the T1- and E1-based infrastructure and serve as layer 3 (the network layer) in the OSI model. Although T1- and E1-based networks employ the *channel associated signaling* (CAS) model, which

Figure 6: A DS-1 superframe structure

Table 1: Allocation of Time Slots in an E-1 Frame

TS0	TS1	...	TS15	TS16	TS17	...	TS31
Framing	Voice Channels				Signaling	Voice Channels	

Figure 7: Internetworking between T1- and E1-based hierarchies

requires the signaling be carried on the same physical medium as that of the data or speech traffic, *broadband integrated services digital network* (BISDN) adopts the *common channel signaling* (CCS) model, which allows the separation of signaling traffic and data or speech traffic and utilizes SS-7 as its signaling protocol. (We will discuss CCS and SS-7 shortly.) For more detailed discussion on BISDN, please refer to Chapter 73 of this handbook.

Plesiochronous Digital Hierarchy

Plesiochronous digital hierarchy (PDH) is the first system designed to transmit voice in PSTN using the digital format. PDH is an asynchronous infrastructure in the sense

that each component—such as exchange, multiplexer, cross-connect, repeater, and so on—gets its clocking pulse from different sources that are synchronous but have minute fluctuations in timing.

PDH defines an integrated digital network that can carry any kind of digital information such as digitized voice, data, and video. PDH also specifies the different transmission levels, or data rates, and the number of channels that can be contained within each level.

Three different standards of the PDH Infrastructure have been adopted in different regions of the world. *T-carriers* adopt the DS-1 frame format and DS-*n* digital hierarchy and are deployed throughout North America. *E-carriers* adopt the CEPT-1 frame format and are deployed throughout Europe and the majority of other nations around the world, including large parts of Asia, Latin America, and Africa. *J-carriers*, only operating in Japan, adopt the DS-1 frame format but follow the J-*n* digital hierarchy. Table 2 summarizes the signal levels and hierarchy supported by each carrier.

Although T-*n* (*n* = 1, 2, 3, 4, 5) means the infrastructure (Bellcore 1994) carrier type or service type, and DS-*n* (*n* = 1,2,3,4,5) is used to indicate the signal level and interface type, they have been used interchangeably in most locations, except where confusion might result. It is also true for CEPT-*n* and E-*n*.

Lower-level signals can be multiplexed to higher-level signals by using multiplexers. Figure 8 (Clark 1996) shows how the North American digital hierarchy works.

Table 2: Signal Rate and Hierarchy

Digital Signal Level	T-Carrier		E-Carrier		J-Carrier	
	Line Rate (Mbps)	Number of DS-0/T-1	Line Rate (Mbps)	Number of E0/E-1	Line Rate (Mbps)	Number of DS-0/J-1
Level 0 (DS-0, CEPT0)	0.064	1/0	0.064	1/0	0.064	1/0
Level 1 (T-1/DS-1, J-1, E-1/CEPT-1)	1.544	24/1	2.048	32/1	1.544	24/1
DS-1-C	3.162	48/2				
Level 2 (T2/DS-2, E2/CEPT2, J-2)	6.312	96/4	8.448	128/4	6.312	96/4
Level 3 (T3/DS-3, E/CEPT3, J-3)	44.736	672/28	34.368	512/16	32.064	480/20
Level 4	274.176	4032/168	139.264	2048/64	97.728	1440/60
Level 5	400.352	6048/252	565.148	8192/256	397.200	5760/240

**Figure 8:** The T-carrier digital hierarchy**PDH Components**

The PDH system depends on the following key components to implement the network.

Transmission Media. PDH signals can be transmitted over a variety of transmission media, depending on the signal rate. For example, T-1, E-1, or J-1 services can be provided over copper pairs; and T3, E3, or J-3, or high rates, can be provisioned over coaxial cable, microwave, or optical fiber. PDH operates on four-wire circuits—that is, it always operates in full duplex mode.

Repeaters. Repeaters are devices that are deployed between exchanges to amplify and regenerate signals.

Channel Service Units. *Channel service units* (CSU) are interfaces that terminate each end of a T-, E-, or J-carrier.

Data Service Units. *Data service units* (DSU) are interfaces that extend data services to the user's premise.

Multiplexers. *Multiplexer* (MUX) devices are used to format higher-level signals from lower-level ones within the digital hierarchy.

Digital Loop Carriers. Also known as remote terminals, or concentrators, *digital loop carriers* (DLCs) are deployed to improve efficiency and reduce costs by reducing the analog facility and sharing pairs among many multiplexed conversations.

Digital Cross-Connects. *Digital cross-connects* (DCCs) are devices that are deployed to cross-connect exchange channels from one facility to another, using their key feature, which is known as *add and drop*. DCCs are used to route or reroute traffic around connection or failure and allow customers to dynamically reconfigure their own networks. Generally, DCCs can provide four levels of switching: between DS-3s and DS-3s (or E-3s and E-3s), between DS-1s and DS-1s (or E-1s and E-1s), between DS-0s and E-0s, and potentially within a DS-0 (E-0) channel.

Synchronous Optical Network and Synchronous Digital Hierarchy

The *synchronous optical network* (SONET) provides digital formats extending to 40 Gbps or more. SONET is a North America standard (Bellcore 1994, GR-253-CORE). The equivalent European format recommended by ITU-T is called *synchronous digital hierarchy* (SDH) (ITU-T 2001, G.703; 2006, G.707). They are similar in frame format and can accommodate the standard DS-*n* or E-*n* line rates. In contrast to PDH, SONET or SDH is a synchronous infrastructure, meaning that each network element draws its clocking pulses from one clocking source.

SONET and SDH Architecture

SONET and SDH introduced the notion of a ring operation to address network survivability by handling rapid restoration. As shown in Figure 9, SONET and SDH nodes are linked by a dual counter-rotating ring of fiber

Figure 9: SONET and SDH ring architecture

pairs. One pair of fibers, where information flows in a clockwise manner, is designated as the *primary fiber*. Designed to carry information in a counter-clockwise manner, the other pair of fibers are called the *protect fiber*. In case the primary fiber is cut between nodes A and B, information can still be delivered from node A to B via a path from A to D to C to B. This dual ring architecture enables immediate recovery—within 50 milliseconds (Bellcore 1994, GR-253)—from small-scale outages. A major disaster may break both rings at the same time, and thus the counter-rotating ring would not ensure network survivability.

SONET and SDH Signal Hierarchy

Similar to PDH, SONET and SDH (ITU-T 1988, G.801) define their size of frame as 125 μ sec. SONET defines a family of signal levels, called *synchronous transport signal* (STS). The basic signal rate is STS-1: 51.840 Mbps (Bellcore 1994, GR-253). The optical counterpart of STS-1 is *optical carrier level 1* (OC-1).

Higher-level SONET signals are obtained by synchronously multiplexing lower-level modules, resulting in STS- N or OC- N signals. The rate of STS- N is N times the rate of STS-1.

SDH refers to its frame as *synchronous transport module* (STM) and defines its lowest line rate as STM-1 at 155.520 Mbps (ITU-T 1988, G.702), which is equivalent to

that of OC-3 or STS-3. Higher-level STM- N signals have line rates of N times the line rate of STM-1.

The signal hierarchy of SONET and SDH is shown in Table 3.

SONET and SDH Frame Format

An STS-1 frame is a specific sequence of 810 bytes, which is divided into transport overhead and payload and can be used to transport DS-3 signals or a variety of sub DS-3 signals if *virtual tributary* (VT) is used. An STS-1 frame, shown in Figure 10 (Bellcore 1994, GR-253-CORE), is constructed as a ninety-column by nine-row structure. The line rate is

$$810 \times 8 \times 8000 = 51.84 \text{ Mbps}$$

A frame is transmitted row by row from top to bottom, and each row is transmitted column by column from left to right.

The first three columns (total 27 bytes) of the STS-1 frame are the *transport overhead*, which is used to carry frame control relative information. The remaining $87 \times 9 = 783$ bytes per frame are allocated to the *synchronous payload envelope* (SPE) signal. This provides a channel capacity of 50.11 Mbps in the STS-1 signal structure for carrying tributary payloads intact across the synchronous network.

An STS- N frame is formed by *byte interleaving* STS-1 and STS- M frames ($M < N$). An STM- N frame is equivalent

Figure 10: SONET STS-1 frame format (B = 8-bit byte)

Table 3: SONET and SDH Signal Hierarchy

OC- N Level	STS- N Electrical Level	STM- N Electrical Level	Line Rate (Mbps)
OC-1	STS-1	(STM-0)	51.48
OC-3	STS-3	STM-1	155.52
OC-12	STS-12	STM-4	622.08
OC-48	STS-48	STM-16	2488.32 (2.5G)
OC-192	STS-192	STM-64	9953.28 (10G)

Figure 11: SONET STS- N frame format ($B = 8$ -bit byte)

to an STS-3 N frame. Figure 11 shows an STS- N frame. Because the frame rate of 8000 frame per second in a STS- N signal is the same as that of the PDH frame rate, a byte within the STS- N structure represents a channel bandwidth of 64 kbps (8 bits/byte \times 8000 bytes/sec). This is the same rate of a PCM voice channel or a DS-0 or E-0 channel.

Virtual Tributary and Virtual Container

The SONET *virtual tributary* (VT) (Bellcore 1994, GR-253) and SDH *virtual container* (VC) (ITU-T 1999, G.708) structures are designed to support sub-STS and sub-STM-1 payloads such as DS-1 and E-1. There are four sizes of VTs—VT1.5, VT2, VT3, and VT6—and four sizes of VCs (VC1–4). Their rates and standards are shown in Table 4.

Key Components

SONET and SDH were built for and largely rely on fiber-optic transmission media. Both systems include a variety of *multiplexers* and digital cross-connects. There are two major categories of SONET and SDH MUXes:

1. *Terminal MUXes* enable signals to move from one optical level to another level.
2. *Add and drop MUXes* (ADMs) facilitate easy dropping and adding of payload and are one of the key building blocks of the SONET and SDH network.

Figure 12 shows the major functionalities of terminal MUX and ADM.

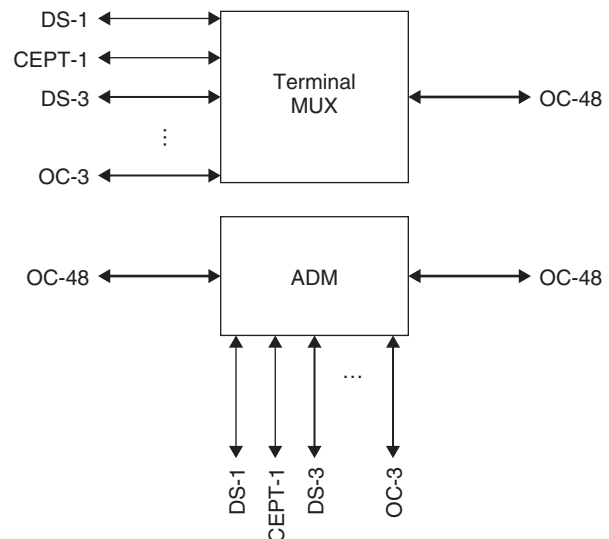

Figure 12: SONET and SDH MUXes versus ADMs

DCCs can also be divided into two categories. *Wide-band DCCs* terminate SONET and SDH and DS-3 and E-3 signals and switch at DS-0, DS-1 and E-1, and VT or VC levels. *Broadband DCCs* interface at various SONET and SDH signal levels as well as the legacy DS-3 and E-3 levels, and can make cross-connections at the DS-3 and E-3 and OC-1 level.

SWITCHING AND SYNCHRONIZATION

Digital Switching

Types of Switching

A digital switch's architecture contains two elements: *time-division switching* (T) and *space-division switching* (S). A switch comprises T and S elements in an arbitrary order. For example, the AT&T number 4 ESS is a TSSSST, 5 ESS is TST, and Nortel DMS-100 is TSTS.

Time-division switching involves time-slot interchange, moving data in each time slot from the incoming bit stream to an outgoing bit stream but in a different order of time slots, in accordance with the preset destination for each time slot.

A T switch, or *time-slot interchanger* (TSI), contains at least two elements: a data buffer and a time-slot controller. The data buffer is used to store the incoming bit

Table 4: SONET and SDH VT and VC

VT/VC Level	Line rate (Mbps)	Standard	Columns in a frame
VT-1.5/VC-1	1.728	DS-1	3
VT-2/VC-2	2.304	E-1	4
VT-3	3.456	DS-1C	6
VT-6	6.912	DS-2	12
Async DS-3/VC-3	44.736/34.368	DS-3/E-3	78/60
VC-4	139.264	DS-4/E-4	243

Figure 13: A simplified diagram of a time switch

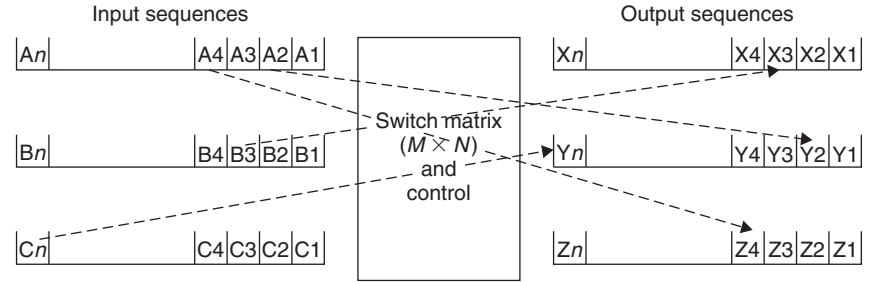

Figure 14: A space switch

stream, and the time-slot controller moves the data in the buffer to the outgoing bit stream in a preset order. This operation is illustrated in Figure 13. The data buffer has the same number of cells as the number of time slots.

Figure 13 shows a single inlet-outlet switch. In case of the DS-1 system, the switch can handle twenty-three stations besides the calling subscriber. To increase the capacity of a switch, a *space switch* (S) is used to move time slots in a trunk to another trunk in the same time-slot position. Figure 14 shows this concept.

The key component of a space switch is a $M \times N$ switch matrix, where M and N represent the number of input trunks and output trunks, respectively. If $M = N$, then the switch is nonblocking (for tandem and transit switches). If $M > N$, then the switch concentrates. If $M < N$, then the switch expands. Local switches usually have $M \neq N$.

Multistage Switches

A digital switch comprises time and space switches in an arbitrary order. Figure 15 illustrates a time-space-time (TST) switch concept. The first stage of the switch is the *time-slot interchangers* (TSI) or time stages that interchange time slots in the time domain between external incoming digital channels and subsequent space stage. The space

stage (a $M \times N$ switch) provides connectivity between time stages at the input and output. When no blocking occurs in the TST switch, the capacity of the TST is $\min(M, N) \times C$, where C is the number of TDM time slots per input trunk. However, blocking can happen in the TST even though the space switch is nonblocking. Blocking occurs in TST if there is no internal space-stage time slot available. During blocking, the link from the inlet time stage and the link to the outlet time stage are both idle. A TST switch is nonblocking if

$$L = 2C - 1$$

where L is the number of space stage time slots, and C is the number of external TDM time slots (Freeman 2004).

A space-time-space (STS) switch is a reversal of a TST switch. It consists of a space switch as the input stage, followed by an array of TSIs whose outputs feed another space switch. Figure 16 shows an STS switch, where the sizes of the two space switch matrices are not necessarily the same.

The architecture of a TST switch is more complicated than that of an STS switch. The TST switch is more cost-effective because time-slot expansion can be achieved at less cost than space expansion. Such expansion is required

Figure 15: A time-space-time switch (TST)

Figure 16: A space-time-space switch

as link utilization increases. Bellamy (2000) states that STS is favored for small switches because of reduced implementation complexities. For large switches with heavy traffic loads, the implementation advantages of TST over STS are dominant. For example, AT&T 5 ESS, a large TST switch, can handle more than 100,000 lines. With a 10:1 concentration rate, 5 ESS can achieve blocking probability of 1.5 percent for an average busy season (AT&T 1994).

Digital Network Synchronization

Needs for Synchronization

When a PCM bit stream is transmitted from one element to another over a link, the transmitter and receiver need to be synchronous to decode the received information. The synchronization has to be done at three levels: bit level, time-slot level, and frame level.

The bit synchronization requires that both the transmitter and the receiver operate at the same rate, and the receiver decodes the bit at the midposition of the incoming bit. Time-slot synchronization is needed but is done when a frame is synchronized.

For the DS-1 frame, there is a frame bit. If the twelve-frame *superframe* (SF) is adopted, it has twelve framing bits. The frame alignment pattern is 101010 and is located in the odd-numbered frames. The superframe-alignment pattern is 001110 and is located in the even-numbered frame. In case of the twenty-four-frame *extended superframe* (ESF), the frame alignment pattern is 001011, and the framing bit occurs only once in four frames.

The E-1 frame has a dedicated framing and synchronization channel in time slot 0 (channel 0). The receiver detects the bit pattern 0011011 in channel 0 from bits 2 to 8 of every other frame. Once this pattern is detected, the receiver knows when the frame starts.

All digital switches have a master clock that is used to clock the outgoing bit stream. The switch also derives the timing from the incoming bit transitions for the incoming bit stream. The standards require that every switch in a digital network generates outgoing bit streams whose bit rate is extremely close to the nominal bit rate. To achieve this goal, all switches in the network have to be synchronized (Bellcore 1994, GR-436). Network synchronization can be accomplished by synchronizing the master clocks in all switch nodes so that each switch node has the same average bit rate. Buffer storage is used at the transmission interface to absorb the differences between the actual line bit rate and the average rate. Without network-wide synchronization, slips will occur.

The other factor to cause slips is *phase wander and jitter* in the digital stream. Phase wander and jitter can be caused by such environmental effects as changing ambient temperature. In case of underflow slips, the last frame just before the clip occurs is repeated. Adequate buffering in the digital line interface can prevent the overflow slips.

Methods of Network Synchronization

There are several methods that can be employed to synchronize the digital networks (ITU-T 1997, G.811; Bellcore 1994, GR-436).

The first method is *plesiochronous operation*. In this case, each switch clock is free running, but each node switch has identical high-stability clocks operating at the nominal rate. The stability of the clock should range from 1E-11 to 5E-13 per month. The disadvantage of this method is that each node has such a high-precision clock, which may incur a high cost burden to a commercial network. This method is popularly deployed in the interfaces between autonomous networks, such as those between LEC and ILCs. ITU-T G.811 (1997) also recommends the plesiochronous operation for international links.

The second method of synchronization is to employ *mutual synchronization* among all network nodes, each of which exchanges frequency references, thereby establishing a common network clock frequency.

The third method to synchronize a digital network is to *synchronize with an external source*, such as geographical positioning system, which disseminates coordinated universal time known as UTC. This method is widely deployed in military systems as well as private networks.

The fourth method used in network synchronization is to *utilize a hierarchical timing distribution system*. This scheme is broadly used in North American networks. Figure 17 shows the synchronization scheme, which is part of a recommendation from Bellcore. In this scenario, different stratum level clocks are deployed at different network nodes. A stratum 1 clock is the *primary reference source* (PRS) of the accuracy of 1E-11 or better. Stratum 2 clocks are typically deployed as part of tandem and transit switches. Stratum 3 clocks are suitable for local exchanges, while stratum 4 clocks are good for channel banks.

The last method for network synchronization is to apply the *master-slave method*. In this scheme, a master clock is synchronized to an external reference, and all other clocks within the network slave to the master clock.

SIGNALING SYSTEMS

The signaling systems are the nerve of the PSTN as network equipment and transmission media are its muscle. A large amount of control information needs to be passed back and forth between network elements to set up and complete a call. Signals can be categorized into four types.

1. *Supervisory signals* handle the on-hook/off-hook condition. When a user picks up a phone handset, an

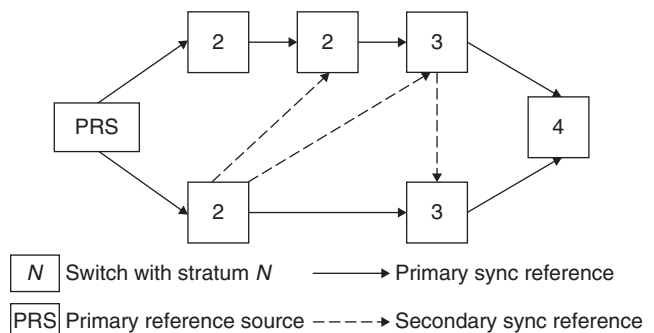

Figure 17: NA hierarchical network synchronization

off-hook signal is sent to the local exchange to indicate that a dial tone is desired. When the call is completed and the user hangs up (on-hook), an on-hook signal is sent to ask to terminate the connection.

2. *Address signals* carry the numbers dialed, including country code, city code, area code, prefix, and subscriber number. The address signal is the routing instruction to the network hierarchy.
3. *Informational signals* provide various enhanced services such as the call waiting service. These signals are optional to set up a call.
4. *Alerting signals* include ringing tones, busy tones, and other alerts.

Signaling takes place in two key parts of the network: (1) in the access network, where it is called *loop signaling*, and can take either analog or digital formats; and (2) in the core, where it is referred to as *interoffice signaling*. There are two mechanisms for interoffice signaling system. One is called *channel associated signaling* (CAS); it sends signals over the same trunk as of the data path. The other is called *common channel signaling* (CCS), and it sends signals over a separate trunk or network to set up and release calls on other trunks. Figure 18 illustrates these two mechanisms.

Signaling in Analog Systems

Many signaling systems have been used in the analog PSTN, including E and M signaling (DC-based signaling) and AC signaling. AC signaling can be further divided into in-band and out-of-band signaling. There are three categories of in-band signaling: *single frequency* (2600 hz), *two frequency* (2400 hz and 2600 hz), and *multifrequency* (MF). Out-of-band signaling is a single frequency system, using 3825 hz for the ITU-T region and 3700 hz for North America.

Despite the many systems, the MF signaling is the only one that is still widely used in current access networks. MF signaling is an in-band system that uses five to six frequencies, two for each tone. ITU-T R1 and R2 are two most popularly deployed MF signaling systems in the access network.

R1: North American MF Signaling

R1 Signaling uses two out of five frequencies (700 hz, 900 hz, 1100 hz, 1300 hz, and 1500 hz) to form the signaling code. Additional signals for control functions are provided by combinations using a sixth frequency (1700 hz). Table 5 contains digits and other control functions and their corresponding frequency pairs.

R2: European MF Signaling

R2 is a European regional signaling code listed in ITU-T Recommendation Q.441. R2 uses full combinations of two out of six tone frequencies to form fifteen frequency pairs. The number of pairs is doubled in each direction by having groups I and II in the forward direction, and groups A and B in the backward direction, as shown in Table 6.

Tables 7 and 8 illustrate the signaling frequencies used in North America. The *dual tone multifrequency* (DTMF) signaling, or so called touch tone, uses seven frequencies and covers ten digits (0–9), “*,” and “#,” as illustrated in Table 7. Also shown in Table 7 is the traditional dial-pulse signaling (i.e., breaks). Table 8 specifies the alerting and call progress signals (Bellcore 1991).

ITU-T Signaling System Number 7

The ITU-T has defined a family of signaling from ITU-T *signaling system number 1* (SS-1) to *signaling system number 7* (SS-7). Among these standards, SS-7 is designed for broadband digital systems and is widely used in the current PSTN (ITU-T 1993, Q.700; ITU-T 1993, Q.703). SS-7 is a CCS-based signaling system that enables the

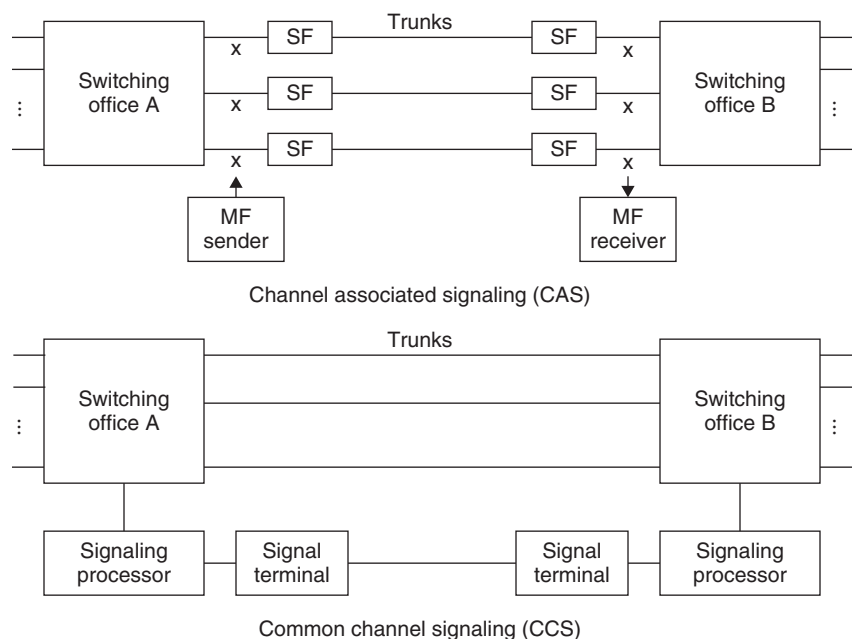

Figure 18: CAS and CCS signaling

Table 5: The R1 signaling code

Digit or special function	Frequency pair (hz)	Description
1	700, 900	
2	700, 1100	
3	900, 1100	
4	700, 1300

ISDN services. SS-7 is also known to have been deployed in a well-defined data network. Each SS-7 link is a full duplex digital transmission channel with bandwidth of 56 kbps (for T- and J-carrier) or 64 kbps (for E-carrier). Multiple voice channels can share a single SS-7 link.

SS-7 Network Architecture

SS-7 itself is a packet-based data network designed to control the operation of the underlying voice networks. A SS-7 network (ITU-T 1993, Q.705) requires three key components: *service switching points (SSPs)*, *service control*

points (SCPs), and *signal transfer points (STPs)*. SSPs and SCPs are the signaling end points of the SS-7 networks. To guarantee the high reliability and high availability of signal delivering, the SS-7 networks adopt a fully redundant architecture as shown in Figure 19.

The STPs and SCPs are usually deployed in pairs, and a backup pair of STPs can be deployed with the primary pair (as shown in the network of carrier 1), thus providing full redundancy of the signal path. SCPs are the centralized nodes that contain the network configuration and call-completion database. STPs are responsible for

**Figure 19:** SS-7 network architecture

interpreting the SS-7 messages and routing them between network nodes and databases. SSPs are the originating and terminating points of calls.

Links in the SS-7 network are designated with particular names according to the network components that they connect.

- A (access) links interconnect STPs and SSPs or SCPs.
- B (bridge) links interconnect primary STP pairs between two carriers or two central offices.
- C (cross) links interconnect the paired STPs.
- D (diagonal) links connect the backup and primary STP pairs.
- E (extended) links connect the SSPs to the backup pair of STPs.
- F (fully associated) links connect two SSPs directly.

SS-7 Structure

SS-7 is internally implemented into a layered structure with two major parts: *message transfer part* (MTP) and *user part* (UP). The MTP can be further divided into three sublayers of *signaling data link*, *signaling link control*, and *signaling network functions*. UPs are classified according to the type of services they support. Currently, three UPs exist: *telephone user part* (TUP), *data user part* (DUP), and *ISDN user part* (ISUP). To facilitate the understanding of the SS-7 layered structure, it can be related to the OSI standard seven-layer networks as shown in Figure 20.

Signaling Data Link. The signaling data link (layer 1) is a full duplex transmission path for signaling, containing two data channels operating together in opposite directions at the same rate. The digital transmission channels may be derived from a multiplex signal at 1.544, 2.048, or 8.448 Mbps having a frame format as defined in ITU G.704 (1998), or they may be from digital multiplex bit streams having a frame structure specified for data circuits in ITU X.50, X.51, X.50 bis, and X.51 bis. The operational signaling data link is exclusively dedicated to the use of SS-7 signaling between two signaling points. No

other information may be carried by the same channels with the signaling information.

Signal Link Control. The signal link control (layer 2) deals with the transfer of signaling messages over one signaling link directly connecting to signaling points. Signaling messages are transferred over the signaling link in variable-length signal units, which include signaling information and transfer control information for proper operation of the signaling link. The signaling link functions include (1) *signaling unit delimitation and alignment*, (2) *error detection and correction*, (3) *initial alignment*, (4) *error monitoring*, and (5) *flow control*.

Signaling Network Functions. The signaling network functions (layer 3) can be broken into two categories: signaling message handling and signaling network management.

Signaling message handling ensures that a signaling message originated by a particular user part is delivered to the same user part at the destination point. Dependent on the environment, the delivery may be through the F links or via one or more STPs.

Signaling network management includes three parts: *signaling traffic management*, *signaling link management*, and *signaling route management*.

Signaling traffic management controls message routing, signaling traffic transfer, and flow control. Signaling link management controls the locally connected signaling link sets. In the event of changes in the availability of a local link set, it initiates and controls actions with the objective of restoring the normal availability of that link set. Signaling route management transfers information about changes in availability of signaling routes in the signaling network to enable the remote signaling points to take appropriate signaling actions.

Signaling Connection Control Part. The *signaling connection control part* (SCCP) (layer 4) provides additional functions to the *message transfer part* (MTP) for both

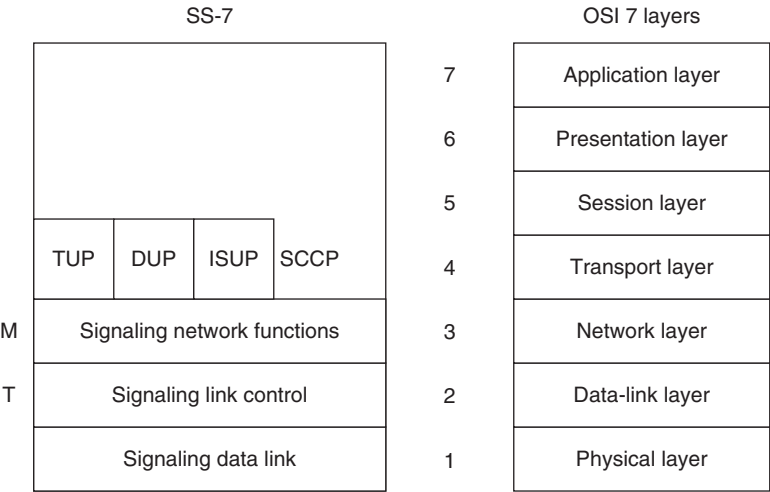

Figure 20: Relationship between SS-7 and OSI model

connectionless and connection-oriented services between switches and specialized centers in telecommunication networks. SCCP mainly provides logical signaling connections within the SS-7 network and a transfer capability for the *network service signaling data units* (NSDUs). Three user parts (UPs) are also supported in the position of SCCP. Each user part corresponds to a specific service, such as the aforementioned TUP, DUP, and ISUP.

NETWORK PERFORMANCE AND MANAGEMENT

Network Performance

Network performance measurements ITU-T G.821 (2002) and G.826 (2002) recommend a set of network performance measurements that should be satisfied by all network elements to guarantee QoS.

Bit error rate or *ratio* (BER) should be less than $1E-6$ in all networks.

Loss of signal (LOS) in the connection is detected by the local exchange.

Alarm indication signal (AIS) is sent from a remote exchange to indicate an alarm condition has been detected.

Errored second (ES) is a one-second period in which one or more bits are in error or during which LOS or AIS is detected.

Severely errored second (SES) is a one-second period that has a bit error ratio? $1E-3 \geq$ or during which LOS or AIS is detected.

Errored second ratio (ESR) is the ratio of ES to the total seconds in the available time during a fixed measurement interval. The performance objective for ESR is < 0.002 .

Severely errored second ratio (SESR) is the ratio of SES to total seconds in available time during a fixed measurement interval. The performance objective for SESR is $ESR < 0.08$.

Unavailable seconds (UAS) are declared when a unidirectional connection experiences ten consecutive SESs and no SES is detected for a period of 10 consecutive seconds. UAS starts at the beginning of the 10 consecutive SESs and ends at the beginning of 10 consecutive non-SESs. For bidirectional connection, the connection is in the unavailable state when either or both directions are in the unavailable state.

Error Detection and Correction Mechanism

Many mechanisms deployed in the PSTN network are used to detect possible bit errors. Most of them can detect or correct one bit error within a frame.

Parity Check. Parity check is a simple mechanism that takes one bit out of an 8-bit byte to avert the parity of the byte. For example, for an even parity-enforced system, a 1010110 string will be appended "0" to keep its even parity. For an odd parity system, a "1" will be appended to make it hold odd number of "1" bit in the byte. This mechanism can only detect an odd number of errors.

Frame Check Sequence. Frame check sequence (FCS) is an error-detection method that sums the 1's in a vertical column of all characters, including the 1's in the eighth bit position. The sum is then appended to the end of the message block. The FCS method can detect one error per bit column.

Cyclic Redundancy Check. Cyclic redundancy check (CRC) is an advanced method that employs complicated algorithms to calculate the FCS, which can be 16- or 32-bits long. The FCS is determined by generating polynomials. ANSI and ITU-T define different generating polynomials. For CRC-16:

$$\text{CRC-ITU-T} = X^{16} + X^{12} + X^5 + 1$$

$$\text{ANSI CRC-16} = X^{16} + X^{15} + X^2 + 1$$

CRC-16 can detect error bursts of as many as 16 bits.

Forward Error Correction. Forward error correction (FEC) uses codes to detect bit errors. Two typical codes are used: block and convolutional. Block codes take k information bits and c parity bits. A Hamming distance is a measure of a code's error detection and correction capability. For example, to detect N erred digits, a Hamming distance of $N + 1$ is required. To correct the error, $2N + 1$ is required.

A convolutional code is formed by convoluting a string of digits with the response function of the encoder. Modulo-2 is used to form check digits.

FEC is good at detecting random errors only. It does not help with burst errors. Some techniques, such as interleaver and deinterleaver, can be used to preprocess the digit stream before they are transmitted and after they are received (Freeman 2004).

Network Management

Basics of Network Management

Network management for PSTN, also known as *surveillance and control* (or SC) in the Bellcore standards (Bellcore 1994, BOC notes), is mainly aimed at maintaining a high level of network utilization efficiency, minimizing the effects of the network overloads, and supporting the Bell operating company's national security emergency preparedness commitment. To achieve these objectives, three important functions need to be implemented: network traffic management (NTM), network service, and service evaluation.

An NTM center provides real-time surveillance and control of message traffic in *local access and transport area* (LATA) telephone networks. The goal of the NTM center is to increase call completions and optimize the use of available trunks and switching equipment. Using information collected from the traffic flows and control capability of the network elements, the operator of the network can optimize the utilization of the network.

Among other functions, the NTM renders relief on traffic overload conditions, including generic network overload, focused overload, and switching system overload.

The reduction of a generic network overload is achieved by deploying techniques such as code blocking, call gapping, and protective trunk group controls. A focused overload, which may result from media stimulation (such as news programs, call-in contests, etc.) or events that cause mass calling to public service agencies, can be managed using code controls or choke networks. Last but not least, NTM can relieve switching system overload, which is caused when the offering load is much higher than the engineered capacity; this is done by employing congestion time-outs with short holding times on the circuit group.

Typical NTM controls are described as follows:

Cancel control prevents overflow traffic from or to a trunk.

Skip route control directs some traffic to bypass a specific circuit group and advance to the next route.

Code block control blocks some percentage of traffic routed to a specific destination code.

Call gapping control uses an adjustable timer to stop all calls to a specific code for a time interval.

Circuit directionalization control changes two-way circuits to one-way operation.

Circuit turndown control removes one- or two-way circuits from service.

Reroute control redirects traffic from congested or failed routes to other groups.

NTM optimizations are based on four principles:

First, keep all trunks filled with messages. Because the network is normally trunk limited, it is beneficial to optimize the ratio of messages to nonmessages on any trunk group. NTM controls are designed to reduce nonmessage traffic flow and allow more call completions, resulting in higher customer satisfaction and increased revenues.

Second, give priority to single-link connections. In a network with alternate-routing support, some calls are alternate routed and therefore must use more than one link to complete a call. During the overload situation, the use of multilinks to complete a call occurs more frequently, and the possibility of a multilink call blocking other call attempts is greatly increased. This is the reason that some NTM blocks a portion of alternate-routed calls to give preference to first-routed traffic.

Third, use available trunking. The network is typically engineered to accommodate average business day peak-hour calling requirements. Focused overloads and holiday calling can cause network failures and switching system outages. In these cases, NTM can be activated to reroute calls to the available trunks.

Fourth, inhibit switching congestion. A large number of ineffective attempts that exceed the engineered capacity of the switching systems can cause switching congestion. NTM can be activated to remove the ineffective attempts.

Network Management Systems

The goal of the *network management system* (NMS) is to provide automated means to remotely monitor a network for (1) level of performance (e.g., BER, ES, LOS, and LOF), (2) equipment failures and circuit outages, and (3) level of traffic load and network usage.

Currently, there are three categories of NMS with respective protocols:

Belcore transaction language 1 (TL1), which is mostly deployed in the North American PSTN;

TCP/IP based simple network management protocol (SNMP); and

ISO -supported common management information protocol (CMIP).

TL1 is a protocol defined in Bellcore's GR-199 (2002), GR-811 (1997), and GR-831 (1996) that imposes syntax, semantics, information structure, and other rules for uniform construction of TL1 messages. TL1 is the most widely used management protocol in telecommunications. It is the telecom industry's only cross-vendor, cross-technology human-machine language that manages the majority of SONET and access infrastructure in North America. In TL1, messages are used to manage the network elements (NEs) and observe faults and events emitted by NEs. In other words, in facilities and equipment that have a TL1 management protocol, TL1 messages are used to operate, administer, maintain, and provision equipment. There are two main types of standards-defined TL1 messages (Bellcore, 1996, 1997, 2002): (1) commands and responses and (2) autonomous events.

Commands and Responses. Commands and responses are initiated by a user and consist of two parts: a request to the NE to get or set information, and a response from the NE containing completion or status codes and requested or chained information.

Autonomous Events. Autonomous events, alarmed or otherwise, are emitted by the NE to indicate some change in its status.

Depending on the TL1 interface for the device, as well as the *element management system* that is used to manage the device, the user executes TL1 requests via a *graphic user interface* (GUI) or a *command line interface* (CLI) and receives notifications from the NE (autonomous events) in a designated location such as stdout, a GUI application, a file, and so on. TL1's widespread acceptance is due in large part to its ease of use. A TL1-conformant message is easy to read, and each message component is easily identifiable. Figure 21 shows an example of a SET ATTR message, which sets alarm condition attributes for specific entities.

Figure 22 shows the basic architecture of a TL1-based NMS. For more details on TL1 message definitions, refer to GR-831 (Bellcore 1996).

SNMP NMS, defined by the Internet Engineering Task Force (IETF), is the most dominant method for devices on a data network to relay network management to the centralized management consoles. The SNMP protocol contains three components: the SNMP protocol itself, the *management information base* (MIB), and the *structure of management information* (SMI). Figure 23 shows the architecture of an SNMP NMS. For details on the SNMP protocols and defined MIBs, see Case et al. (1996a, 1996b, 1996c).

Common Management Information Protocol NMS.

Common management information protocol (CMIP) is an ISO development designed to operate in the OSI environment. CMIP uses *managed objects* (MOs) to model platforms and devices (Warrier et al. 1990). Each CMIP agent maintains a *management information tree* (MIT). CMIP is used to create, change, delete, and retrieve MOs in the MIT.

CMIP is a more versatile protocol but requires approximately five times as much memory as SNMP. It is much more complex than SNMP. Although SNMP uses connectionless transport protocols (UDP and TCP) to transport messages, CMIP relies on standard OSI layers for communication and utilizes connection-oriented transport. For more information about CMIP, see Aidarous and Plevyak (1993).

CONCLUSION

This chapter has briefly discussed the basic concepts of the PSTN network, including its service provisioning, network architectures, frame formats, transport mechanisms, synchronization mechanisms, signaling systems, network performance measurement, and network management. PSTN is an evolving network that has adopted new available technology and facilities—such as digital cross-connect, SONET, fiber optics, and so on—to increase its capacities and enhance its services.

A significant trend in PSTN development is the evolution to the *next generation network* (NGN). ITU defines NGN as a packet-based network that provides full services of voice, data, video, multimedia, and mobility. Users of NGN should be offered unrestricted access to different service providers. The next generation gateway switches will provide seamless interoperability between the circuits that connect PSTN and packet-switching networks such as IP backbones, ATM networks, and MLPS networks. They will support a variety of telephony signaling protocols such as H.323, *session initiation protocol* (SIP), and *media gateway control protocol* (MGCP) for communicating with the underlying SS-7 architecture. SS-7 signaling will continue to play a key role in NGN, supporting packet-based telephony networks using class 4 (toll) and class 5 (local exchange) switches.

NGN will support at least these features: (1) a packet-switching network with capacity in the range of terabits per second (TBPS) or more; (2) an optical-based core network to take advantages of the abundant bandwidth in the light spectrum; (3) multiservice access with intelligent networking applied to the public data infrastructure as well as the Internet; and (4) access moving toward the broadband realm on both a wire and wireless basis. To include access, edge, core, and service layers, a complete NGN PSTN transformation can be spread over several years.

GLOSSARY

Central office (CO): A physical location where local service providers terminate subscriber lines and locate the switching equipment that interconnects those lines.

Channel associated signaling (CAS): An electronic means of signaling in which the signal is carried on the same physical path as the data.

Common channel signaling (CCS): An electronic means of signaling between any two switching systems that is independent of the voice path.

Competitive local exchange carrier (CLEC): A telephone company that competes with an ILEC.

Customer premise equipment (CPE): Equipment that is located on the customer's premises and is owned and managed by the customer.

Digital loop carrier (DLC): A type of concentrator; also known as a *remote concentrator*.

Dual tone multifrequency (DTMF): A method of signaling that uses two frequencies to stand for a key on the keypad.

E-n: A time-division multiplexed, digital transmission facility that operates at an aggregate rate of multiples of 2.048 Mbps. E-carrier is a PCM system that uses 64 kbps (E-0) for a voice channel. The basic E level is E-0 (64 kbps); higher levels are E-1 (2.048 Mbps), E-2 (8.488 Mbps), and so on.

Incumbent local exchange carrier (ILEC): A telephone company that provides local service in the United States; came into existence after enactment of the Telecommunications Act of 1996.

Interchange carrier (IXC): A long-distance telephone company that offers circuit-switched, leased-line, or packet-switched services.

Plesiochronous digital hierarchy (PDH): The first generation of digital hierarchy that defines transmission rates and frame formats; that is, T-carrier for North America, E-carrier for ITU-T countries, and J-carrier for Japan.

Private branch exchange (PBX): A telephone switch that is located on the customer's premises and establishes voice circuits between users.

Public switched telephone network (PSTN): The complete traditional public telephone system that includes the telephones and local and interchange trunks.

Pulse code modulation (PCM): A scheme that is used to convert a voice signal into a digital bit stream for transmission. A common method to digitize the speech is to use an 8-bit code word and sampling at 8000 times per second to produce the basic rate of 64 kbps.

Signaling system number 7 (SS-7): A telecommunication signaling protocol defined by the ITU-T. The SS-7 architecture is set up in a way so that any node can exchange signaling with any other SS-7 signaling-enabled node, not just signaling between switches that are directly connected.

Synchronous digital hierarchy (SDH): An ITU-T standard for digital broadband communications.

Synchronous optical network (SONET): An ANSI standard that has been incorporated into the SDH standard and that defines a line-rate hierarchy and frame formats for use with high-speed optical fiber.

T-n: The North American standard of the PDH, a time-division multiplexed, digital transmission system. The T-carrier is a PCM system that uses 64 kbps (T-0) per channel as the basis of the hierarchy. The higher rates are T-1 (1.544 Mbps), T-2 (6.312 Mbps), and so on.

INTRODUCTION

In his classic paper, Shannon (1948) states, "The fundamental problem of communication is that of reproducing at one point either exactly or approximately a message selected at another point."

Beginning from this premise, Shannon proceeded to develop a beautiful, coherent, and surprisingly complete mathematical theory of communication. In this chapter, we outline some of the key elements of Shannon's theory and then turn our attention to a wide array of related topics. Although some of these related topics might go slightly beyond the usual definition of information theory, all are relevant to topics that appear in this volume.

SHANNON'S THEORY

Background and Basics

The diagram in Figure 1 models a general communication system. As the diagram shows, errors may occur during transmission because of the "noise source."

Figure 1: Communication system

Each block in Figure 1 will be discussed to some extent in this chapter. The topic of this section—Shannon's theory—deals with the "transmitter → channel → receiver" path and the effect of noise on this crucial part of a communication system.

Channel Capacity

Suppose that we transmit seven-bit ASCII characters using eight bits for each (there is one parity bit) over a 1 Mb/sec link. Then we are able to transmit $1,000,000(7/8) = 875,000$ bits of information per second; this is the channel capacity, C . Note that the capacity is not the number of bits transmitted, but the number of information bits transmitted.

More generally, the transmitted symbols need not all be of the same length. In this case, we define the capacity as

$$C = \lim_{T \rightarrow \infty} \frac{\log N(T)}{T}$$

where $N(T)$ is the number of different symbol strings of length T . When \log is taken to be \log_2 , this formula gives the correct result in the case where the symbols are all of the same length. This is often the case of interest in modern communications systems where bits, bytes, (fixed size) packets, and so on are transmitted.

Entropy

Entropy is the fundamental concept of Shannon's theory. At the time Shannon developed his mathematical theory of

communication, the term *entropy* was established and widely used in physics. Why did Shannon choose to use the same term for his new concept? According to Tribus and McIrvine (1971), Shannon said that

My greatest concern was what to call it. I thought of calling it “information,” but the word was overly used, so I decided to call it “uncertainty.” John von Neumann had a better idea. [H]e told me, “You should call it entropy, for two reasons. In the first place your uncertainty function goes by that name in statistical mechanics. In the second place, and more important, nobody knows what entropy really is, so in a debate you will always have the advantage.”

Why is uncertainty the “right” thing to measure? One of the fundamental problems Shannon was concerned with was compression. To compress data, we compress the redundant information—that is, the parts that are “certain” or knowable from other parts of the data can be removed. At the extreme, if we have a string of bits that will always be all 1’s, then it has no uncertainty (equivalently, it is entirely redundant, and we say that its entropy is zero), and this string compresses to nothing. In other words, we do not even need to transmit the string at all because it is entirely known to the sender and receive beforehand. On the other hand, if we have a random string of bits, with all bit strings being equally probable, then, on average, such a string will not compress.

Let X be a random variable. Then we denote the entropy of X as $H(X)$. We define entropy with respect to an underlying probability distribution. This assures us that the entropy will not change because of a trivial change such as a change of label from “bits” to “heads or tails.” We also denote the entropy function as $H(p_0, p_1, \dots, p_{n-1})$, where the arguments p_i are the underlying probabilities—that is, each p_i is nonnegative and the sum of the probabilities is 1.

What properties should the entropy function $H(X)$ satisfy? We would like the function to satisfy the following conditions.

First, the function $H(p_0, p_1, \dots, p_{n-1})$ should be a real-valued continuous function of its arguments. This is desirable because, intuitively, a small change in the arguments should result in a small change in the function value.

Second, if all outcomes are equally likely, then the more outcomes there are, the larger the entropy—that is, $H(1/n, 1/n, \dots, 1/n) \leq H(1/(n+1), 1/(n+1), \dots, 1/(n+1))$. For example, if we flip a fair coin, there are only two possible outcomes whereas when we roll a die there are six possible outcomes, so the outcome of a roll of a die is more uncertain than the outcome when a coin is flipped.

Third, if an outcome is viewed as the result of successive outcomes, then the original entropy H is the weighted sum of the entropies leading to the outcome. For example, suppose that we roll a die and the three outcomes of interest are “even,” {1,3}, and {5}. Then the entropy function for this experiment is $H(1/2, 1/3, 1/6)$. On the other hand, we could view this same experiment as having outcomes “even” and “odd,” with the “odd” outcome being

further split into {1,3} and {5}. The probabilities in these two cases are illustrated below.

In this case, we require that $H(1/2, 1/3, 1/6) = H(1/2, 1/2) + 1/2H(1/3, 2/3)$. In general, we require that $H(p_0, \dots, qp_j, (1-q)p_j, \dots, p_{n-1}) = H(p_0, \dots, p_j, \dots, p_{n-1}) + p_jH(q, 1-q)$ for $0 < q < 1$. Because these experiments are equivalent, we clearly want the entropies to be the same. The point of this assumption is that we want the entropy to be linear in this specific sense.

Shannon (1948) proved the following result.

Theorem: The only H satisfying the three assumptions above is of the form

$$H(p_0, p_1, \dots, p_{n-1}) = -K \sum_{i=0}^{n-1} p_i \log p_i$$

where K is a positive constant.

We choose $K = 1$, and we take \log to be \log_2 , which yields the entropy function $H(p_0, p_1, \dots, p_{n-1}) = -\sum p_i \log_2 p_i$. Note that because of the choice of logarithm, the entropy can be measured in bits as discussed above.

In any experiment with n equally likely outcomes, we have

$$H(p_0, p_1, \dots, p_{n-1}) = -\log(1/n) = \log n$$

For example, if we flip a fair coin, there is one bit of uncertainty, and the entropy in this case is indeed 1. On the other hand, rolling a single die has entropy of $\log 6 = 2.58$. In this way, we can quantify the increased uncertainty of a roll of a die as compared to a flip of a coin.

Entropy has many equivalent interpretations. One interesting interpretation is that, roughly speaking, entropy gives the minimum number of yes-no questions that need to be asked to determine an outcome (Trappe and Washington 2002). For example, suppose that we flip two fair coins and count the number of heads. Then the entropy is:

$$-1/4 \log 1/4 - 1/2 \log 1/2 - 1/4 \log 1/4 = 3/2$$

In this case, we can determine the actual number of heads with, on average, 1.5 questions as follows. First, we ask, “Is the number of heads odd?” If the answer is yes (which occurs with probability 1/2), then we are done; if not, it takes one more question to precisely determine the number of heads.

Entropy is also the number of bits of information inherent in a given outcome. When we flip three fair coins, the entropy is three; in any particular flip of three fair coins, we thus learn three bits of information. Similarly, the entropy is the minimum number of bits required to represent an event on a digital computer.

In other words, the uncertain bits are all that need to be stored because any remaining parts are completely predictable. Therefore, entropy is intimately related to data compression.

As an illustrative example, we now briefly consider the entropy of English while simultaneously defining additional concepts related to entropy. Suppose we eliminate all punctuation, special characters, and spaces and use only lowercase letters. With these restrictions, English text is limited to twenty-six characters. If the individual letters were independent, then the entropy per letter would simply be $-\sum p_i \log p_i$, where p_i is the probability of the i th letter. If all letters were equally likely, then this would yield an entropy value of $1/26 \sum \log 26 = 4.7$, which implies that there are approximately 4.7 bits of uncertainty in each letter. But in English text the letters do not each occur with an equal probability. In a large selection of English text, the letter “e” will have a frequency of more than 12 percent, while “q” will appear far less than 1 percent of the time. Taking these relative frequencies into account, the entropy of English is reduced to approximately 4.2—that is, there are only some 4.2 bits of uncertainty per letter.

In reality, there are far less than 4.2 bits of uncertainty per letter of English text. For example, the letter “x” is unlikely to be followed by the letter “z,” while the letter “q” is extremely likely to be followed by “u.” This information is not accounted for in the entropy calculation based on individual letter frequencies. To account for such information, we need to consider the 26^2 digraphs, aa, ab, ac, ..., zz and compute the entropy of each letter, given the previous letter. But then we can make the same argument regarding trigraphs, quadgraphs, and so on. As a result, the precise entropy of English would need to be calculated as $\lim_{N \rightarrow \infty} \frac{H(N)}{N}$, where $H(N)$ is the entropy of English N -graphs.

It is only practical to enumerate English N -graphs for small values of N , so it appears that a reasonable estimate of the entropy of English might be difficult to obtain. However, Shannon (1951) proposed the following practical approach to obtain an upper bound on the entropy of English. Suppose we have a deterministic machine that will predict the next letter of an English text based on the previous letters. Given an English text, the predictor machine is used to make guesses until the next letter is guessed correctly. Once the letter is guessed correctly, we record the number of guesses required, the letter is revealed, and the machine is then used to guess the next letter. This process continues until we have obtained a sequence of numbers (the numbers of guesses) corresponding to the sequence of letters. Then the original text can be reconstructed directly from the sequence of numbers using the predictor machine. Therefore, the entropy of English can be no greater than the entropy of the sequence of numbers.

Now suppose that we replace the predictor machine with an English-speaking human. The sequence of number is no longer sufficient to reconstruct the text—because of the nondeterministic nature of humans—but the resulting sequence of numbers should still provide a reasonable approximation because English-speaking

humans provide a reasonable approximation to a predictor machine. Using this approach (with humans), we can simply use the relative frequency of each number that occurs and thereby approximate the entropy of English. This experiment yields an estimate of the entropy of English text of slightly more than one bit per letter.

Consider the *relative entropy* of English text—that is, the fraction of uncertainty (or information) in English letters relative to the uncertainty of random text, which, as noted above, has the maximum possible uncertainty. This relative entropy is given by $\frac{H}{\log(26)}$, where H is the en-

tropy of English text. Let $R = 1 - \frac{H}{\log(26)}$. Then R is the

fraction of English that is certain, and therefore R , or the *redundancy*, gives the fraction of English text that does not carry any information. For English, we have $R \approx 0.75$, which, among other things, implies that, optimally, we should be able to compress English text by a ratio of approximately 4 to 1. Huffman coding comes reasonably close to achieving this theoretical bound.

Shannon (1948) discusses several “interesting properties” of his entropy function, H , that we briefly summarize here.

1. We have $H = 0$ only when there is no uncertainty in the outcome. More precisely, $H = 0$ if and only if $p_i = 1$ and $p_j = 0$ for all $j \neq i$.
2. The entropy H is maximized when the uncertainty with respect to the underlying probability distribution is maximized. This follows from the fact that, for a given n , the value of H is maximized at $\log n$ precisely when $p_i = 1/n$ for all i , which is the most uncertain case.
3. The entropy of a joint event is never more than the sum of the entropies of the individual events. Consider, for example, an event X with n possible outcomes and an event Y with m possible outcomes, with joint probability distribution $p(i, j)$. Then

$$H(X, Y) = -\sum_{i,j} p(i, j) \log p(i, j)$$

and it is not difficult to see that

$$H(X) = -\sum_{i,j} p(i, j) \log \sum_j p(i, j)$$

and

$$H(Y) = -\sum_{i,j} p(i, j) \log \sum_i p(i, j)$$

From these expressions it follows that $H(X, Y) \leq H(X) + H(Y)$.

4. The more uniform the probabilities, the greater the entropy. For example, if p_1 and p_2 are both replaced with $(p_1 + p_2)/2$, then the new entropy will be at least as great as the original entropy.

5. Consider two random variables, X and Y , as in property 3 above, where X and Y need not be independent. The conditional entropy of Y , denoted $H(Y|X)$, should measure the amount of uncertainty in Y , given knowledge of X . The conditional probability of the event that Y is j given that X is i is given by

$$p_i(j) = p(i, j) / \sum_j p(i, j)$$

Then the conditional entropy of Y given X is defined as

$$H(Y|X) = -\sum_{ij} p(i, j) \log p_i(j)$$

In words, the conditional entropy measures the uncertainty of Y , on average, when X is known. It is easily shown that $H(X, Y) = H(X) + H(Y|X)$. This important result means that the uncertainty in the joint event is given by the uncertainty of X plus the uncertainty of Y when X is known.

6. Combining properties 3 and 5 yields $H(Y|X) \leq H(Y)$. This matches with the intuition that knowledge of X cannot increase the uncertainty of Y . In fact, $H(Y|X) < H(Y)$ unless X and Y are independent, in which case equality holds.

Noise and the Fundamental Theorem

Here we present a simple example of a noisy channel and consider the role that entropy has to play in such a situation. Then we give Shannon's fundamental theorem and mention one of its implications.

Shannon (1948) considers the following example of a noisy channel. Suppose we have a source that transmits bits at a rate of 1000 per second with an equal probability for 0 and 1. Suppose that during transmission, errors occur, so that 1 percent of the bits are received in error. Clearly, the rate of transmission of information is less than 1000 bits per second, but how much less? Because we expect 10 errors in each 1000 transmitted bits, the "obvious" answer is 990 bits per second, but this fails to account for the fact that the receiver does not know a priori which bits are correct and which are in error. In the extreme, suppose that the received bits are random with equal probability of 0 and 1. Then approximately 500 bits would be "received" correctly; but we certainly cannot claim that 500 bits of information was transmitted, because the same result would be obtained by simply flipping a coin at the receiving end.

Shannon defines the rate of information transmission as $R = H(X) - H(X|Y)$ —that is, the rate at which information is transmitted is the rate at which it was sent, $H(X)$, minus the information that is "missing" at the received end, which can be viewed as the ambiguity in the received signal. The conditional entropy $H(X|Y)$, which goes by the name of *equivocation*, measures the uncertainty in X , given the received signal Y . In the example above, with a 1 percent chance of error, if a 0 is received, then it is 99 percent certain that a 0 was sent and a 1 percent chance that a 1 was sent (and vice versa in the case

where a 1 is received). Consequently, the equivocation in this example is

$$H(X|Y) = -(0.99 \log_2 0.99 + 0.01 \log_2 0.01) \approx 0.081$$

This gives the number of bits of uncertainty per symbol. Because one bit of information is transmitted per symbol and 1000 bits per second are sent, the rate of transmission of information is $1000 - 81 = 919$ bits per second. On the other hand, if the received bits are random, then the equivocation would be

$$H(X|Y) = -(0.5 \log 0.5 + 0.5 \log 0.5) = 1$$

in which case, $1000 - 1000 = 0$ bits of information are transmitted. This agrees with our intuition that no information has been transmitted in such a scenario.

Define the capacity of a discrete channel with noise as $C = \max (H(X) - H(X|Y))$, where the maximum is over possible information sources to the given channel. In the case where there is no noise, $H(X|Y) = 0$, and the capacity is simply the maximum amount of information that can be fed into the channel, which is consistent with the definition of capacity given above. If $H(X|Y) > 0$, then the capacity is reduced by a corresponding amount. Shannon's fundamental theorem states that it is possible to send information through the channel at the rate C "with as small a frequency of errors or equivocation as desired" (Shannon 1948). However, if we try to send information at rate $C + R$ through the channel, then the equivocation must be at least R . Shannon's fundamental theorem can be stated as follows.

Theorem: Let a discrete channel have capacity C and a discrete source have entropy (per second) of H . If $H \leq C$, then there exists a coding system such that the output of the source can be transmitted over the channel with an arbitrarily small frequency of errors (or an arbitrarily small equivocation). If $H > C$, it is possible to encode the source so that the equivocation is less than $H - C + \epsilon$, where ϵ is arbitrarily small. There is no method of encoding that gives an equivocation less than $H - C$.

One consequence of Shannon's fundamental theorem is that "good" error correcting codes exist. However, Shannon's proof of this theorem does not provide a particularly useful road map for constructing such codes. An enormous amount of research has been conducted since the initial publication of this result in an effort to find codes that approach the bound promised by Shannon.

This completes our brief overview of Shannon's theory. For more details on the basic theory, Shannon (1948) remains surprisingly relevant, readable, and concise. Numerous sources discuss the theory and extend it in various directions. The book by Trappe and Washington (2002) has a brief but highly readable introduction to various mathematical aspects of the theory; MacKay (2002) contains a thorough treatment of the basic theory and includes many fascinating advanced topics; and the books by Ash (1990), Cover and Thomas (1991), and Reza (1994) are just a few of the many other excellent sources available.

DIGITAL SAMPLING OF SIGNALS

Most modern communication networks have increasingly migrated to digital, rather than analog, signal formats for several important reasons. The processing speed and data throughput rates of general purpose computers and *digital signal processors* (DSPs) have grown exponentially over recent years. The relatively lower cost of designing, fabricating, assembling, and maintaining digital electronics has won out over that of systemwide custom analog circuitry. Digital systems offer more modularity and scalability, and they permit more efficient communications channel utilization via packetized transport mechanisms, and broadband, spread spectrum, frequency-hopping methods.

Modern electronic circuits sample analog signals at discrete time intervals, usually with uniform temporal spacing. It is no surprise that such a circuit is called an *analog-to-digital converter* (ADC). It can be implemented using many different methods, including successive approximation, flash (totem-pole comparator configurations), sigma-delta feedback, and multistage error correction (Frerking 1994; Brannon 1995). A high-quality ADC can be an extremely expensive electrical circuit component, relatively speaking. Thus, different designs make various trade-offs among conversion rate, precision (bit depth dynamic range), accuracy (faithful representation of the actual input value), and cost. One must analyze carefully the actual requirements dictated by the particular application in order to choose wisely an appropriate ADC component.

There are other, less obvious, issues regarding ADC performance. First, note that the digital amplitude is quantized discretely into 2^n levels, where n is the number of ADC output bits. However, it is easy to show that the statistically averaged resolution of the ADC is roughly one-third of a bit. Consider the probability distribution, whereby an analog signal value x ranges uniformly between a digital output transition amplitude of magnitude ka to $(k+1)a$, with k being a positive integer, as given in Figure 2.

We can calculate the statistical root-mean-square (RMS) error σ_x as follows. First,

$$\begin{aligned} \int_{ka}^{(k+1)a} P(x) dx &= \frac{1}{a} [(k+1)a - ka] = 1, \text{ so that } \langle x \rangle \\ &\equiv \int_{ka}^{(k+1)a} xP(x) dx = \frac{1}{a} \left[\frac{x^2}{2} \right]_{ka}^{(k+1)a} = \frac{1}{2} (2k+1)a \end{aligned}$$

Figure 2: Probability for analog signal x to cause digital transition level a

and

$$\langle x^2 \rangle \equiv \int_{ka}^{(k+1)a} x^2 P(x) dx = \frac{1}{a} \left[\frac{x^3}{3} \right]_{ka}^{(k+1)a} = \frac{1}{3} (3k^2 + 3k + 1) a^2$$

Then the variance is given by

$$\begin{aligned} \sigma_x^2 &\equiv \int_{ka}^{(k+1)a} (x - \langle x \rangle)^2 P(x) dx = \langle x^2 \rangle - 2\langle x \rangle^2 + \langle x \rangle^2 \\ &= \langle x^2 \rangle - \langle x \rangle^2 \end{aligned}$$

Its square root, or RMS value, which measures the standard deviation, is

$$\sigma_x^2 \equiv a^2 \left\{ \frac{1}{3} (3k^2 + 3k + 1) - \frac{1}{4} (4k^2 + 4k + 1) \right\} = \frac{1}{12} a^2$$

Finally, we have

$$\sigma_x = \frac{1}{\sqrt{12}} a \approx \frac{1}{3} a \quad (\text{roughly speaking})$$

Several important issues affect ADC performance. Major influences include sampling time jitter, sample and hold circuitry time jitter, limited slewing rate for tracking rapid changes in signal amplitude, nonlinear response in the circuitry, and spurs in frequency response resulting from clock harmonic noise components (Brannon 1995; Frerking 1994; Masta 1999; Oppenheim, Schaffer, and Buck 1999). It is surprising that many of these problems can be minimized by dithering the sampled signal with a small amount of asynchronous noise. In fact, the noise can be as large as a full amplitude quantization level.

The added noise offers two main benefits. First, it tends to smooth out large, abrupt jumps in output level in the time domain. Second, it reduces the harmonic spurs in the frequency domain at the minor expense of raising the overall asynchronous spectral noise floor. Dither noise can be provided by means as simple as using a noisy high-impedance input resistor. A more sophisticated approach involves using a linear feedback shift register (LFSR) to generate a pseudo-random number generator with a long repetition period in the digital output stage. More details may be found in the references cited above.

Time Domain Representation

Many interesting analog signals vary relatively smoothly with time and are often quasi-periodic in nature. This suggests the utility of a truncated Fourier series in order to allow a limited number of terms in approximating the analog signal well. Later we will examine some other important representations for describing analog signals. In general, we can use any complete set of orthonormal functions as a basis for the representation of a signal.

We often use a sinusoidal representation for an analog signal, using real-valued functions $a(t)$ for amplitude and $\phi(t)$ for phase.

The *instantaneous amplitude* is $x(t) = a(t)e^{i\phi(t)}$. The *instantaneous frequency* is given by $f(t) = \frac{1}{2\pi} \frac{d\phi(t)}{dt}$. We

will see that one cannot simultaneously specify both the amplitude and frequency without some fundamental limitations on their relative precision. If the signal is not complex, as is often the case, then one can simply take the real part of $x(t)$. Traditional methods of broadcasting radio signals modulate a carrier wave by changing $a(t)$ in the case of amplitude modulation (AM), and $\sigma(t)$ in the case of frequency modulation (FM). AM signals use a constant carrier wave frequency, $f(t) = f_c$. FM signals use a constant amplitude, $a(t) = a_c$. Nevertheless, in both cases the signal spectrum will occupy a range of frequencies, or bandwidth, centered about the carrier wave frequency. If the carrier wave frequency is zero, then the signal is said to be *basebanded*.

We usually work with signals that have limited time duration or frequency bandwidth. We will see that each of these limited intervals affects the other. When the analog signal is sampled at discrete intervals, the representation changes from a continuous function $x(t)$ to a finite length sequence of n values, $x_0, x_1, x_2, \dots, x_{n-1}$.

Major considerations for discrete sampling of analog signals include dynamic range and sampling rate. The particular application will dictate an appropriate cost and performance trade-off with respect to ADC bit depth, speed, and precision. In the case of dynamic range, one must adjust the gain properly to map the full analog amplitude range without clipping to utilize all of the ADC bits. The sampling rate must be at least twice the Nyquist frequency. One must usually employ an analog low-pass filter before the ADC to reject unwanted high-frequency signals and avoid aliasing in the captured spectrum. As an alternative, one can oversample the analog signal, apply a digital low-pass filter after the ADC, and decimate the filtered digital signal, retaining only a smaller bandwidth of interest. In a similar way, signals generated by modulating a very-high-frequency carrier wave can be basebanded via analog input circuits before discrete sampling at lower rates, or else oversampled at higher rates and basebanded via digital postprocessing. We will discuss this in more detail in a later section.

Frequency Domain Representation

All signals that we process will be limited necessarily in both temporal duration and frequency bandwidth. One can view the power density of a sampled signal as being distributed either in the time domain or in the frequency domain. These viewpoints are complementary but distinct representations of the signal. We will see that merely by limiting the time duration of a sampled signal, a *monochromatic* tone will spread in the frequency domain. Similarly, limiting the frequency bandwidth of a signal will be accompanied by a spread, or *uncertainty*, in temporal localization and duration.

Discrete Fourier Transform

Given a continuous time-domain analog signal $x(t)$, one can convert it to its equivalent counterpart, $X(f)$, in the

frequency domain, and vice-versa, by means of the continuous Fourier transform pair. The formulas relating these two are

$$X(f) = \int_{-\infty}^{+\infty} x(t) e^{+i2\pi ft} dt$$

and

$$x(t) = \int_{-\infty}^{+\infty} X(f) e^{-i2\pi ft} df$$

These transforms are linear in the sense that the transform of a sum of signals is equal to the sum of the transforms of each signal individually. This follows easily from the definitions because

$$\int_{-\infty}^{+\infty} (a(t) + b(t)) e^{+i2\pi ft} dt = \int_{-\infty}^{+\infty} a(t) e^{+i2\pi ft} dt + \int_{-\infty}^{+\infty} b(t) e^{+i2\pi ft} dt$$

and

$$\int_{-\infty}^{+\infty} (A(f) + B(f)) e^{-i2\pi ft} df = \int_{-\infty}^{+\infty} A(f) e^{-i2\pi ft} df + \int_{-\infty}^{+\infty} B(f) e^{-i2\pi ft} df$$

Signals that are discretely sampled in the time domain as a sequence of n amplitude values $x_0, x_1, x_2, \dots, x_{n-1}$ require some modifications to this Fourier transform pair. Specifically, in the discrete case, we have

$$X_k = \sum_{j=0}^{n-1} x_j e^{+i2\pi jk/n}$$

and

$$x_j = \frac{1}{n} \sum_{k=0}^{n-1} X_k e^{-i2\pi jk/n}$$

We will see later that an optimal choice for the number of samples is such that n is a power of 2. Note that a finite length sequence of discretely sampled data is necessarily periodic with period n .

The so-called Fourier kernel or twiddle factor— $e^{\pm i2\pi jk/n}$ —comprises the n th roots of unity, lying on the unit circle in the complex plane. Nicely detailed analyses of these concepts can be found in Frerking (1994); Krauss, Shure, and Little (1998); Oppenheim, Schaffer, and Buck (1999); Press et al. (1992); Reid and Passin (1991).

If we call the uniform time sampling interval $\Delta t = \tau$, with total sampled time duration $n\tau$, then the uniform frequency sampling interval is given by $\Delta f = 1/(n\tau)$. The Nyquist frequency is given by $f_N = n\Delta f/2 = 1/(2\tau)$. Note that this dimensional information does not appear explicitly in the abstract formulas specified by the *discrete Fourier transform* (DFT) pair. The DFT maps the n values $x_j = x(t_j)$, with $0 \leq j \leq (n-1)$, into n values $y_k = y(f_k)$, with $0 \leq k \leq (n-1)$. The sequence of time values at which the signal is sampled is given by $t_j = 0, \tau, 2\tau, \dots, (n-1)\tau$. However, the input signal must be band limited to avoid aliasing, such that $|f_k| \leq f_N = n\Delta f/2 = 1/(2\tau)$, for all k . The factor of 2 in the denominator of this relation reveals that negative, as well as positive, frequencies are needed to completely specify the frequency domain representation of a (complex-valued) signal. Hence, the sequence of frequency values at which the signal is sampled is given by:

$$\begin{aligned} f_k &= \pm 0, +1/(n\tau), \dots, +[(n/2)-1]/(n\tau), \pm 1/(2\tau) \\ &= \pm f_N, -[(n/2)-1]/(n\tau), \dots, -1/(n\tau) \end{aligned}$$

This arrangement of terms is often called *wraparound order*. The frequency terms rise in value from $+0$ to $+f_N$, jump to $-f_N$, then increase back up to -0 . There are two redundancies: one at $+0 \Leftrightarrow -0$ and another at $+f_N \Leftrightarrow -f_N$. This is somewhat bizarre, and hence given the special, albeit appropriate, name of *wraparound order*. The name seems to arise from the fact that as the negative frequency abscissas rise toward zero, they actually decrease in modulus. It is important for at least two reasons. First, it explicitly indicates that sampling needs to be done at more than twice the Nyquist frequency because we get equal amounts of positive and negative frequency abscissas. Second, the wraparound speaks to the finite, discrete sampling, giving rise to periodicity, and the danger of aliasing, should we neglect to band limit the signal. The aliased frequencies first add onto and corrupt the edges of the interval near DC. As their frequency increases, they corrupt more of the interval toward the Nyquist frequency in the middle from either or both ends. Just as a finite length sequence of discretely sampled data in the time domain is necessarily periodic with period n , so too is the frequency domain representation.

If the signal time-domain amplitudes are real-valued, then the frequency domain values are complex conjugate pairs, symmetric about $f = 0$, i.e., $y_{(m+n/2)} + y_{(-m+n/2)}^*$, with $0 < m < n/2$. Furthermore, y_0 and $y_{(n/2)}$ are each self-conjugate and hence real-valued. This is perhaps more obvious when one examines the following relations for the continuous Fourier transform pair. We have

$$X(f) = \int_{-\infty}^{+\infty} x(t) e^{+i2\pi ft} dt, X^*(f) = \int_{-\infty}^{+\infty} x^*(t) e^{-i2\pi ft} dt$$

and $x^*(t) = x(t)$, so that

$$X^*(f) = \int_{-\infty}^{+\infty} x^*(t) e^{-i2\pi ft} dt = \int_{-\infty}^{+\infty} x(t) e^{+i2\pi(-f)t} dt = X(-f)$$

Processing Overhead

The formulas for the DFT indicate a sum of n terms, each of which involves a multiply and accumulate (MAC) calculation. Furthermore, there are n such sums. Thus, a brute force computation is of polynomial order of complexity $O(n^2)$. However, there exists a clever, recursive algorithm, called the *fast Fourier transform* (FFT), popularized by Cooley and Tukey (1965). This algorithm reduces the order of complexity to $O(n \log_2 n)$ (Frerking 1994; Krauss, Shure, and Little 1998; Oppenheim, Schaffer, and Buck 1999; Press et al. 1992; Reid and Passin 1991). The method entails repeated subdivision of the DFT into interleaved even and odd terms, dividing the complexity by a factor of 2 at each subdivision. This technique effectively reduces the DFT summation to $O(\log_2 n)$. However, there are still n sums to calculate, and hence the overall computation is $O(n \log_2 n)$. For this method to succeed, it is imperative that n be an exact power of 2. If the number of data samples does not satisfy this criterion initially, then it is advantageous to enforce the criterion, by either adding extra data samples with zero value (zero padding) or throwing some data samples away.

When the number of data samples is extremely large, it is often necessary to break the data set into smaller subsets and apply a smaller length DFT to each data subset. This is clearly necessary when sampling a data stream for a long period of time. In that case, it is important not only to reduce processing overhead, but also to track spectral data characteristics that are changing with time. The most commonly used method for breaking the data stream into subsets is to use a *sliding buffer frame*. Usually, it is recommended that there be a 50 percent overlap between successive data frames. In this case, overlapped results are added together. This technique also mitigates issues variously called *ringing transients*, *Gibb's phenomena*, or *diffraction anomalies* associated with sharp cutoffs in the data stream. A better technique for eliminating undesirable effects due to sharp cutoffs in the data stream is to employ *windowing*, discussed in a later section, which effectively smooths the data at the edges of the sliding frame buffer. Finally, one can alternatively use zero padding of each successive frame buffer instead of overlapping adjacent buffers.

The effect of sharp cutoffs is particularly noticeable in some images published by newspapers. Some images are compressed tightly for transmission over a satellite communications channel with limited bandwidth, using the lossy compression afforded by the ubiquitous JPEG algorithm (Pennebaker and Mitchell 1992). JPEG compresses eight-by-eight blocks of pixels successively without overlap or windowing. High-compression ratios yield visual *blocking* anomalies by which image contrast levels change abruptly.

Performance can also be greatly enhanced by using modern processor hardware architectures. Several key developments specifically address the type of calculation required to perform DFTs. Special processor instruction sets include MAC operations and so-called barrel-shifted addressing modes to unwind the interleaved nature of the recursive FFT algorithm. The chain of self-similar MAC operations lends itself well to *single-instruction*,

multiple-data (SIMD) architectures. Processors with *reduced instruction set computing* (RISC) architectures easily permit data pipelines, effectively reducing MAC overhead to a single machine clock cycle after initial setup. Often one can simultaneously decode a data sample's memory address, load an earlier data sample into a register, and perform a MAC operation on an earlier data sample—all in a single clock cycle. A common processor architecture feature that improves throughput is inclusion of multiple execution units on the same die. Another improvement stems from utilization of multiple address and data buses. Finally, some architectures use vector, or array, processors on the die. These architectural enhancements were formerly unique to highly specialized *digital signal processors* (DSPs). However, nowadays even general purpose commodity processors, such as Power PCs and Pentiums, include these improvements.

Correlation Operator and Power Spectrum

The correlation operator is often used to compare one signal against another for a match. Common applications include signal detection and analysis used in radar and sonar (Oppenheim, Schaffer, and Buck 1999; Oppenheim 1978). One is usually interested in shifts in time or frequency between the two signals. A shift in time, or lag, may provide information such as target range, because of the finite speed of signal propagation. A change in frequency may provide information such as target speed resulting from the Doppler shift. The time domain formulas for the continuous and discrete correlation are given as a function of lag by

$$r(t) = \int_{-\infty}^{+\infty} a(t + \tau) b(\tau) d\tau$$

and

$$r_k = \sum_{j=0}^{n-1} a_{k+j} b_j$$

respectively.

Note that each finite-length, discretely sampled signal sequence is necessarily periodic, and thus there are wrap-around issues. Thus, if $(k + j) \geq n$, then $a_{(k+j)} = a_{(k+j-n)}$. In addition, the time lags represented by r_k are arranged in wraparound fashion. Thus, positive lags occur for $0 < k < n/2$, negative lags occur for $n/2 < k < n$, $r_{+0} = r_{-0}$, and $r_{+n/2} = r_{-n/2}$. If one wishes to circumvent the periodic nature of the finite sample sequence, one must zero pad the frame buffer to the larger length $(2n - 1)$. However, the end points of the resulting correlation will have large errors of estimation because fewer data points actually enter into the calculation for large values of lag.

FFT methods can play an important role here because of frequency domain properties of the correlation operator. If $A(f)$, $B(f)$ are the Fourier transforms of the time domain signals $a(t)$, $b(t)$, then the Fourier transform of their correlation is given simply as the product $C(f) = A(f)B(-f)$. Recall that if the time domain signal is real-valued, then

$B(-f) = B^*(f)$, and thus $C(f) = A(f)B^*(f)$ in that common situation. One can often obtain significant performance gains by transforming into the frequency domain, calculating the product, and then transforming back to the time domain to find the time lag response of the correlation in the now familiar wraparound order.

When one correlates the signal with itself—a process called the *autocorrelation*—one can measure the overall power in the signal. The total power can be obtained by integrating the differential *power spectral density* (PSD) over the full range in either the time or the frequency domain. According to Parseval's theorem, this must remain invariant, whether calculated in the time domain or in the frequency domain. The power density per unit time is given by $|x(t)|^2$ in the continuous case or $|x_j|^2$ in the discrete case. The power density per unit frequency is given by $|X(f)|^2$ in the continuous case or $(1/n)|X_k|^2$ in the discrete case. Recall that if the signal is real, then $X^*(f) = X(-f)$, or $X_k^* = X_{(n-k-1)}$, when $0 < k < (n - 1)$. In the discrete case, $X_0 = X_0^*$ and $X_{n-1} = X_{n-1}^*$ are real-valued. Then the total power is, in the continuous case,

$$\int_{-\infty}^{+\infty} |x(t)|^2 dt = \int_{-\infty}^{+\infty} |X(f)|^2 df$$

while in the discrete case it is given by

$$\sum_{j=0}^{n-1} |x_j|^2 = \frac{1}{n} \sum_{k=0}^{n-1} |X_k|^2$$

Sensor Characteristics

Ideal sensors would have perfect calibration accuracy and extremely fine-grained precision. Alas, ideal sensors do not exist. Calibration can be a thorny issue if the sensor response varies nonlinearly over the full dynamic range. Improper calibration gives rise to systematic error offsets. Sophisticated detection circuitry, or postprocessing following detection, can ameliorate this problem. A simple example is afforded by the audio cassette. Because of the limitations in high-frequency response and dynamic range of audiotape magnetic storage, the signal is *companded*, or reduced in dynamic range when recorded on tape, and expanded during playback. In addition, different tape technologies require different bias and equalization.

Another problem with nonideal sensors is limited precision or resolution. The response function is necessarily smeared because of statistical error in the signal-detection process. The detector output can be represented mathematically by the convolution of the actual signal and the sensor response function. This operation is described in the next section. In theory, it is possible to deconvolute the sensor response function from the detected signal to obtain a more ideal signal representation. However, this process is fraught with peril. One issue stems from the need for detailed information concerning the sensor response function over a wide range of operating characteristics. Another issue stems from inadvertent introduction of noise and systematic uncertainty via deconvolution where the signal-to-noise ratio is small. One

popular technique for such a deconvolution process is called *optimal Wiener filtering* (Krauss, Shure, and Little 1998; Press et al. 1992).

Convolution Operation

The convolution operation is mathematically similar to the correlation operation. In practice, however, these two operations have quite different applications. The correlation operation is used to evaluate the degree of match between a measured signal and a reference signal. Radar signals reflected from a target can reveal its range and speed via correlation with the transmitted signal. The convolution operation is commonly used to model the smeared response function of an imperfect detection process. In the case of convolution, the response function is time-reversed—that is,

$$\nu(t) = \int_{-\infty}^{+\infty} a(t - \tau) b(\tau) d\tau$$

and

$$\nu_k = \sum_{j=0}^{n-1} a_{k-j} b_j$$

The time reversal results from the time-ordered manner in which the smeared detector response function samples the signal. However, mathematically the convolution result remains invariant whether one time reverses the response function or the signal.

Usually, the response function has a smaller period than that of the signal and must be zero padded to have the same length as the sequence of signal samples. The periodic nature of the discrete representations yields wraparound properties similar to those that arose in the case of the correlation operator. There is also a corresponding relationship in the frequency domain. If $A(f)$, $B(f)$, $V(f)$ are the Fourier transforms of $a(t)$, $b(t)$, $\nu(t)$, then $V(f) = A(f)B(f)$. Thus, here again, we may profitably employ the FFT to reduce significantly the overall computation load.

Sampling Issues

There are special requirements for a discretely sampled sequence to accurately represent a continuous analog

signal. The sampling rate must exceed twice the Nyquist frequency: $f_s \geq 2f_N$. The analog signal must be bandwidth-limited via filtering so that its highest frequency component is less than the Nyquist frequency: $|f_{\max}| \leq f_N$. Nevertheless, there are issues associated with finite, quantized intervals in both the time domain and the frequency domain. For example, the sampling rate will dictate the width of the frequency bins, thus determining the frequency resolution. The location of the bin edges can influence the interpretation of the power spectral density, $|X(f)|^2$. Therefore, several nearby narrowband frequency spikes in the signal being sampled may become smeared together in the discrete power spectral density periodogram. Oversampling—namely, choosing $f_s \gg 2f_N$ —can improve spectral resolution but incurs a processing performance penalty. Oversampling can assist in resolving nearby frequency spikes but may not provide a clear separation if the spikes occur close to bin edges. We will consider these issues in more detail below, illustrating the nature of these problems, and suggest methods to ameliorate their influence (Krauss, Shure, and Little 1998).

Figure 3 shows a “pure tone” at 1 kHz, the peak sensitivity of the human auditory system, with a duration of ten periods. Note that the real part of the frequency domain amplitude spreads or leaks symmetrically around the central maximum at 1 kHz. This effect occurs both in the continuous and (necessarily) the discrete sampled signal domains. Figure 4 illustrates the same 1-kHz tone with twice the duration of twenty periods.

Figure 4 illustrates an “intrinsic” increase in absolute frequency resolution in the continuous domain. The mathematical function that describes the form of the power spectral density in the frequency domain is related to the transcendental function called *sinc*. (A popular electronics store in Silicon Valley has adopted this shape as an architectural embellishment.) We have $x(t) = e^{-i2\pi f_0 t}$ and

$$X(f) = \int_0^{mT} x(t) e^{+i2\pi f t} dt \quad \text{and, hence,}$$

$$\begin{aligned} X(f) &= \left[\frac{1}{2\pi(f - f_0)} e^{+i2\pi(f - f_0)t} \right]_0^{mT} \\ &= \frac{1}{2\pi(f - f_0)} [e^{+i2\pi(f - f_0)mT} - 1] \end{aligned}$$

Figure 3: Simple tone, frequency = 1000 hz, duration = 10 periods

Figure 4: Simple tone, frequency = 1000 hz, duration = 20 periods

It follows that

$$|X(f)|^2 = X(f)X^*(f) = \frac{1}{2} \left[\frac{1}{\pi(f-f_0)} \right]^2 \times [1 - \cos(2\pi(f-f_0)mT)] = \left[\frac{\sin(\pi(f-f_0)mT)}{\pi(f-f_0)} \right]^2$$

The multiplier m in the numerator of $|X(f)|^2$ provides the resolution enhancement in the power spectral density in the frequency domain. There is a reciprocal relationship between the spread in the time domain and the spread in the frequency domain representations of the signal. This relationship is the basic idea behind the Heisenberg uncertainty principle in quantum mechanics. It is possible to quantify this result mathematically (Messiah 2000; Reid and Passin 1991; Reza 1994). We can calculate the standard deviation, or root-mean-square, for the time spread as well as for the frequency spread:

$$\sigma_t^2 \equiv \langle t^2 \rangle - \langle t \rangle^2 = \int_{-\infty}^{+\infty} (t - \langle t \rangle)^2 |x(t)|^2 dt \text{ and}$$

$$\sigma_f^2 \equiv \langle f^2 \rangle - \langle f \rangle^2 = \int_{-\infty}^{+\infty} (f - \langle f \rangle)^2 |X(f)|^2 df$$

The inequality $\sigma_t \sigma_f \geq \frac{1}{4\pi}$ follows from a Cauchy-Schwarz relation.

Quantum mechanics associates the energy of a system with a wavelike frequency through the relation $E = hf$. Here h is Planck's constant, the quantum scale parameter, which has the units of angular momentum. This theory also associates physical observables with linear operators in an abstract Hilbert space. The spectra of these operators, or *eigenvalues*, are the possible measured values for the associated physical observable *eigenstates*. Operators that cannot be simultaneously diagonalizable do not commute and give rise to the Heisenberg uncertainty principle—that is,

$$\sigma_E \sigma_p \geq \frac{h}{4\pi} = \frac{\hbar}{2} \text{ and } \sigma_x \sigma_p \geq \frac{h}{4\pi} = \frac{\hbar}{2}$$

where E is energy, p is linear momentum, and $\hbar = h/(2\pi)$.

This principle points out that, because of particle-wave duality, one cannot simultaneously localize, with unlimited precision, physical quantities associated with complementary representations, such as energy (frequency) and time or position and momentum. These conclusions follow directly from the probabilistic nature of measurement in quantum mechanics, as well as from its fundamental postulates. Information theory is concerned mainly with the probabilistic nature of measurement. However, there are additional important considerations regarding causality, because of relativity theory, which states that information cannot be transferred faster than the speed of light. Recent theoretical work and experimental evidence have established the validity of the quantum entanglement of states and confirm a strict interpretation of quantum theory. These developments refute the Einstein-Podolsky-Rosen (1935) conjecture, which favored undiscovered “hidden variables,” in opposition to a probabilistic theory. These recent results, as well as relativity theory, also dismiss more fanciful notions such as superluminal communication. More information on theoretical and experimental results can be found in selected references such as Bell (1964); Aspect, Grangier, and Roger (1982); and Tittel (1998). A particularly approachable book for popular audiences is the delightful historical analysis by Aczel (2003). These principles constitute the foundations for quantum information theory and quantum cryptography (more properly termed *quantum key exchange*).

Returning to the classical physics domain, there are important practical considerations that stem from the analogy of the uncertainty principle. Because of spectral leakage into nearby frequency bins, one may be tempted to increase the sampling rate or increase the number of the samples per frame buffer (or both). The first method can mitigate problems with the analog filtering in the input stage by increasing the Nyquist frequency or else provide finer-grained frequency bins if the Nyquist frequency is held constant. Note, however, that increasing the sampling rate, while holding the Nyquist frequency constant, does not reduce the spectral leakage into nearby bins. Instead, the bins simply have smaller intrinsic width (Press et al. 1992). The second method statistically improves intrinsic spectral resolution at the expense of slower tracking of spectral changes in nonstationary signals. There is yet another method to assist interpretation of the power spectral density, called *windowing*, described in the next section.

Figure 5: Window shapes in time domain

Data Block Windowing

Many windowing or envelope functions are employed to taper off the amplitude range of a signal frame buffer at its initial and final temporal domain values. Figures 3 and 4 used a boxcar window. In general, one can reduce spectral width of the main frequency lobe by choosing a window with a narrow central peak and rapid fall-off on either side. However, the windowed signal displays larger spectral leakage into sideband frequencies. Following from Figure 5, we see that Figures 6 and 7 indicate the main frequency lobe as the leftmost peak. The side lobes caused by leakage extend to the right. These observations follow directly from the “uncertainty principle” inequality outlined above. An “optimal” trade-off between main lobe resolution and side-lobe leakage can be achieved by using a Gaussian or bell-shaped window function that corresponds to exact equality in the “uncertainty principle” formula. In other words, the Fourier transform of a Gaussian curve also has a Gaussian shape. A Gaussian distribution for the random variable x , with mean $\langle x \rangle$, and standard deviation σ_x , is given by

$$g(x) = \frac{1}{\sqrt{2\pi}\sigma_x} e^{-\frac{(x-\langle x \rangle)^2}{2\sigma_x^2}}$$

However, the exponential function results in a costly calculation penalty so that similarly shaped approximations are used in practice. A linear triangular window, obtained by integrating (smoothing) a boxcar, still has an awkward cusp. Thus, one usually resorts to smoother, nonlinear window functions. Common functional shapes include truncated polynomial series for trigonometric functions (Hamming, Blackman) or Bessel functions (Kaiser). The Kaiser window can be adjusted to have a large central width (small b parameter) or a small central width (large b parameter). Figures 5, 6, and 7 illustrate the window shapes in the time domain and their corresponding frequency response (Krauss, Shure, and Little 1998). In all cases, one must trade off narrowness of a spectral peak

Figure 6: Window frequency response (boxcar, triangle)

Figure 7: Window frequency response (Hamming, Blackman, Kaiser)

against sideband ripple by adjusting the window shapes accordingly. Note also the potential for problematic spurs in the frequency domain in Figures 5, 6, and 7.

SIGNAL CODING

Some excellent sources for more detailed information on coding theory are MacKay (2002), Press et al. (1992), Reza (1994), Trappe and Washington (2002). Of course, there are many other good sources in books, articles, and on the Internet.

Most familiar data types contain a lot of redundant information. A simple example is written language. One can omit most vowels (but not consonants) of longer words in written language and still permit meaningful information transfer. For example, given the vowel-less text

Th qck brwn fx jmpd vr th lz dg

it is not difficult to determine that the original text was

The quick brown fox jumped over the lazy dog.

In musical chords, an analogous phenomenon occurs when a note or two are excised yet the human auditory perceptual process fills in the missing tones, especially a pleasant-sounding phantom fifth interval.

Depending on the structure of the data messages and contextual usage, one can apply a variety of coding techniques to reduce information entropy and necessary transmission bandwidth. It is clear that this goal is desirable to improve channel efficiency. In addition, it opens up headroom for additional “out of band” information that can be used for error detection or correction in noisy channels and control signals to be transmitted along with the message data information.

Error-detection techniques are usually varied according to the nature of the encoded signal. These methods are closely tied to various forms of error correction used in practice. One rather simple technique for mitigating errors is repetition of message packets, followed by majority logic processing. This is often called *message redundancy*. Another popular technique is retransmission via a handshake between sender and receiver. In this scenario, a second smaller code is encapsulated within the message packet to verify integrity. Common verification codes include parity bits, checksums, cyclic redundancy codes, and hash functions. All of these techniques have different trade-offs in efficiency and robustness. Extremely noisy channels obviously reduce effective transmission bandwidth dramatically, necessitating hardware upgrades or simultaneous transmission over multiple redundant pathways.

Real-Valued Scalar Signals

Most sensor data consist of real-valued quantities. However, this is not always the case, particularly in the case of digital radio frequency transmissions. Earlier we described a commonly used circular function representation for an analog signal using real-valued functions $a(t)$ for amplitude and $\phi(t)$ for phase, where $x(t) = a(t)e^{i\phi(t)}$ and $f(t) = \frac{1}{2\pi} \frac{d\phi(t)}{dt}$.

We can represent a noncomplex sinusoid simply by taking the real part, $\text{Re}(x(t))$. Conversely, one can convert a real-valued signal to an analytic complex-valued signal by using a Hilbert transform. The term *analytic* is used in the strict mathematical sense, as defined in the theory of complex-valued functions of complex variables. It is often more convenient to manipulate complex-valued functions (required to be analytic). This technique is introduced early in courses of study in analog electronics, optics, and so on. More information can be found in Frerking (1994); Krauss, Shure, and Little (1998); and Oppenheim, Schaffer, and Buck (1999).

Modern digital hardware has become extremely computationally fast and inexpensive. Thus, nowadays specialized sensors bridge the domains between an analog signal source and a digital input to digital processors, both general and specialized in nature. Only a few decades ago, it

was customary to perform computationally complex operations such as the FFT by utilizing specially fabricated piezoelectric quartz crystals, with nonlinear time delay, called *surface acoustic wave* (SAW) processors.

Most people nowadays, of course, focus attention on the digital data stream. Digital signal processing has become the dominant method because of many factors, including low cost, modularity, scalability, and reduced calibration and maintenance costs.

Real-valued signals possess a unique symmetry in their frequency domain representation. Recall that, given a continuous time-domain analog signal $x(t)$, one can convert it to its equivalent counterpart $X(f)$ in the frequency domain, and vice-versa, by means of a continuous Fourier transform pair. In the case of real-valued signals, $x^*(t) = x(t)$. Then, from the definition of the Fourier transform,

$$X(f) = \int_{-\infty}^{+\infty} x(t) e^{+i2\pi ft} dt$$

we have

$$X^*(f) = \int_{-\infty}^{+\infty} x^*(t) e^{-i2\pi ft} dt = \int_{-\infty}^{+\infty} x(t) e^{+i2\pi(-f)t} dt = X(-f)$$

from which it easily follows that $X^*(+f) = X(-f)$. Of course, the same type of symmetry occurs for discretely sampled real-valued signals.

Complex-Valued Signals

As discussed above, mathematical operations on complex-valued signals tend to be more tractable. There are important cases where the complex-valued representation of signals are necessary. One example is a 120-V AC, 60-hz current in a power line that possesses both amplitude and phase. Another example is an optical signal, comprising coupled varying electric and magnetic fields. An optical signal possesses yet another important property—polarization—because a light quantum, or photon, has nonzero spin angular momentum ($s = 1\hbar$). A technical point is that a photon, being massless, travels at the speed of light. Thus, it possesses only two, rather than three, polarization states. Different representations for these two orthogonal polarization states commonly use either [vertical planar, horizontal planar] or [left circular, right circular]. We use the term *optical* broadly to cover the full range of the electromagnetic (EM) spectrum. EM signals commonly in use range from khz to Mhz to Ghz and beyond (e.g., high-energy gamma rays). Technically, the power line signal is merely an extremely low-frequency optical signal.

I/Q Representation of Signals

In many important situations it is necessary to use complex-valued signals whose real and imaginary parts do not obey the symmetries discussed earlier. In other words, $x^*(t) \neq x(t)$ and $X^*(+f) \neq X(-f)$. However, we usually

want to enforce an analyticity condition on signals of interest. The analyticity condition imposes a causal behavior on such signals as well as enforcing more “well-behaved” mathematical properties. The analyticity condition can be enforced either by Hilbert transformer circuitry in the case of continuous domain signals or a digital Hilbert transform in the case of discretely sampled signals. For such signals in the time domain, the real part is commonly called “I,” while the imaginary part is called “Q.” These symbols were defined for historical reasons to specify the in-phase and quadrature components (the latter meaning 90 degrees out of phase). Much more information may be found in Frerking (1994).

There is a different kind of “symmetry” (perhaps better called “broken symmetry”) for analytic complex-valued signals. For this kind of signal, one can choose between two different and distinct possible situations for the frequency domain representation: All negative frequency components are zero $X(-f) = 0$ or (exclusive or) all positive frequency components are zero $X(+f) = 0$. This condition is critically important for shifting signals up in frequency from baseband or shifting them down toward baseband. In other words, modulating or demodulating a carrier wave with the signal of interest does not incur a penalty of spectral reflections. One can also multiplex many band-limited signals onto a single higher-bandwidth communication channel.

To illustrate the importance of this type of signal (besides the case of cable TV), consider *magnetic resonance imaging* (MRI) diagnostic medical equipment. Magnetic Resonance Imaging is a less popularly frightening term than the underlying physics of *nuclear magnetic resonance* (NMR). Human bodies are mostly water, whose molecules consist of two hydrogen atoms and one oxygen atom. The nucleus of a hydrogen atom is a single proton, which possesses a nonzero spin angular momentum. Such objects in most cases rotate in the presence of an external magnetic field like a compass needle in the Earth’s magnetic field. Furthermore, it is possible to alter the proton’s precession by resonant absorption of an RF signal (Mhz range). One can detect the weak excitation and subsequent relaxation of the proton’s precession to diagnose tumors and even monitor metabolic processes dynamically in real time on TV.

Digital Modulation Schemes

Several signal-modulation schemes are (perhaps) more complicated than either AM or FM. Here we consider two specific examples of digital modulation, namely, pulse code modulation and quadrature amplitude modulation.

Earlier we discussed (implicitly) *pulse code modulation* (PCM). This is simply the digital sampling and quantization of analog signal streams at regular intervals. When people “rip” audio tracks from CDs, they extract the digitized audio. However, the PCM stream is usually repackaged with wrappers into a segmented data structure. The resulting file has a different internal structure, depending on certain standards. The standards are provided mainly by the operating system vendor rather than by the actual software-ripping application. In the case of audio CDs, the PCM-modulated data consist of two interleaved

(stereo) streams. Each PCM stream is discretely sampled at a rate of 44.100 khz and a range of 16 bits. Thus, theoretically, the Nyquist frequency is 22.050 khz, and the dynamic range is 96 dB. Of course, the actual, as opposed to theoretical, bandwidth and dynamic range are somewhat smaller, depending on the instrumentation and recording equipment.

The theoretical bandwidth far exceeds the hearing range of most people, except perhaps for gifted children. An interesting consequence of the theoretical 96 dB dynamic range is that one often needs to keep turning the audio playback amplifier gain up (to hear the quieter sections) or down (to avoid ear damage). There is so much headroom, that many people reduce it by subsequently compressing it with perceptual filters. Of course, the other reason for compression is to reduce the file size by roughly a factor of ten.

Quadrature amplitude modulation (QAM) performs a mixture of two different signals 90 degrees out of phase. The term *quadrature* arises from the fact that the two signals are orthogonal. It is desirable, because it affords a minimal bandwidth over wires. By using a multisymbol constellation in the I/Q domain, the bandwidth requirement is reduced. Depending on the noise in the channel, one may need to employ a smaller number of symbols. This affords a smaller chance of intersymbol errors. QAM is used for encoding the two TV chroma signals. It was also used for transmitting data over 9600 bits per second (bps) telephone lines. More information can be found in Frerking (1994) and Krauss, Shure, and Little (1998). An example of a QAM constellation appears in Figure 8. In this case, each symbol is represented by four different values for both I and Q. This popular modulation scheme is called 16-QAM because it encodes sixteen distinct four-bit symbols.

Figure 8: QAM (I/Q) constellation

Parity Bits

Parity bits constitute an extremely simple coding method. One merely adds all individual binary bits in a digital message packet using mod 2 arithmetic. This is equivalent to applying right or left shifts, masking off either the *least significant bit* (lsb) or the *most significant bit* (msb), and XOR ing the bit in an accumulator. This is a highly efficient calculation for digital processors. For example, a digital byte 10110011 yields a parity bit 1, while a byte with an even number of one bits yields a parity bit of 0. Sending a single parity bit per byte can detect a transmission error. However, it cannot perform correction because it is unclear which bit, including the parity bit, flipped during transmission. Sending more parity bits by breaking up the byte into overlapping fragments can offer more robust error correction but the overhead becomes quite large.

Checksums

A common checksum involves adding each n -word sequence into a one-word accumulator. This is attractive from both the standpoint of computational efficiency and small packet-size augmentation. It can determine fairly reliable occurrences of message packet corruption but offers little chance of error correction. Retransmission via handshake can recover a corrected message packet.

Hash Functions

Cryptographically secure hash functions are a type of checksum. Most hashes, like checksums, produce a result that has smaller measure than the message used as input to the hash function. This is a mapping from a larger space to a smaller space—that is, a many-to-one function. It is clear that many different messages can produce the same hash code, called a *collision*, as illustrated in Figure 9. However, good hash functions are designed so that it is computationally infeasible to find any two messages with the same hash value. Thus, it is common practice to transmit both a message and its hash to ensure that no transmission error or tampering has occurred in transit. Many software distributions employ this method, often using the hash function *message digest algorithm 5* (MD5).

Figure 9: Hash collisions

A collision was recently discovered for MD5, so it is now considered “broken.” Another popular standard, the *secure hash algorithm 1* (SHA-1), has also been broken recently. Although no SHA-1 collision has yet appeared (as of the time this chapter was written), it is clear that an actual collision will soon be found. More information can be found in Wang and Yu (2005).

A useful feature of hash functions is randomization as well as message-size reduction. In other words, the same message may be mapped to different hashes in a pseudo-random fashion by including a short random value known as a “salt.”

All checksum techniques are able to detect certain types of random errors. In addition to the detection of random errors, cryptographic hash functions provide the ability to detect malicious tampering. In other words, for most checksum methods, an intelligent adversary can change a message in a way that a checksum remains valid. But if a cryptographically secure hash function is used, any change to the data will result in a different checksum.

Cyclic Redundancy Codes

Cyclic redundancy codes (CRCs) are designed to offer a degree of simple error correction as well as detection. However, because they are based on linear operations, the error-detection feature is vulnerable to spoofing by an adversary. A highly useful feature of CRCs is that their mathematical calculations can be implemented efficiently in digital hardware.

Cyclic codes (CC) are aptly named in the sense that any cyclic permutation of a member's elements yields another member of that code. Let element X_0 be a member of cyclic code C , $X_0 \in C$, $X_0 = (x_0, x_1, x_2, \dots, x_n) \in C$, then also $X_2 \in C$, where $X_2 = (x_2, x_3, x_3, \dots, x_n, x_0, x_1)$, and so forth for all cyclic permutations.

CRCs are a specific type of CCs. The most commonly used representation to implement a CRC employs fixed-length linear combinations of polynomial terms. Each term in the linear combination corresponds to an increasing power (by one integral unit). Given an element X of a code C , $X \in C$, we can realize its implementation by

$$X = \sum_{k=0}^{n-1} a_k z^k = a_0 z^0 + a_1 z^1 + \dots + a_{n-1} z^{n-1}$$

The polynomials are defined over a finite field. Specifically, calculations employ modular arithmetic based on polynomial division. Usually, the coefficient for each polynomial term uses mod 2 arithmetic, being either 0 or 1. For more information, see Press et al. (1992), Stamp (2005), and Trappe and Washington (2002).

Gray Codes

Gray codes, named after Frank Gray, were designed at Bell Labs in the mid-twentieth century (Gray 1953). They helped mitigate the occasional large data errors caused by a single bit flip in a noisy channel. For instance, in ones-complement representation, a decimal 8 is represented as binary 1000, while flipping the msb yields binary 0000, which is equivalent to decimal 0. This is a shift of eight decimal units. The ones-complement representation

increments the least significant bit by one bit, with a carry to the next most significant bit, as the decimal count increases by one. This is a natural coding technique because it maps our usual radix-10 integer counting system directly into the corresponding radix-2 integer counting system. In contrast, the Gray code sequence for decimal 0, 1, ..., 8, increases as 0000, 0001, 0011, 0010, 0110, 0111, 0101, 0100, 1100. Note that each successive term in the sequence differs by only a single bit with respect to its neighbors both left and right.

The pattern may seem peculiar at first, but there is an interesting underlying structure. In ones-complement representation, bit 0 has a cycle of one, bit 1 has a cycle of two, bit 2 has a cycle of four, and so forth. In the Gray code, bit 0 has a cycle of two, bit 1 has a cycle of four, bit 2 has a cycle of eight, and so forth. The Gray code can be implemented efficiently in digital hardware by using a recursive, reflection-about-the-midpoint algorithm. More details can be found in Frerking (1994), Press et al. (1992), and Trappe and Washington (2002).

Hamming Codes

Hamming Codes (Hamming 1980) were also designed at Bell Labs in the mid-twentieth century. There is some confusion, concerning prior art versus official publication, for a large number of clever coding techniques around this time. The major players, in alphabetic order, are Golay, Golomb, Gray, Hamming, Shannon, and unnamed others.

Hamming codes—more precisely, the Hamming [7,4] code—maps four input bits into a seven-bit output code word. The structure of this mapping is a linear transformation (nonsquare matrix), from a four-dimensional space to a seven-dimensional space. It is clear that the overhead involved nearly doubles the transmission bandwidth. However, the significant benefit is that this method can correct a single-bit error and detect a double-bit error. The method used to find the flipped bit is to apply a linear operator (nonsquare matrix), derived from the encoding matrix, to the received code word. If the three-bit result is (0,0,0), then no error occurred. If any result bit is nonzero, then one uses a lookup table (dictionary) to determine the flipped bit.

A four-bit message vector can be converted into a seven-bit Hamming codeword by multiplying (mod 2) on the right by the following matrix:

$$\begin{bmatrix} 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}$$

Error detection and correction can be performed by multiplying (mod 2) the transmitted seven-bit code word on the right by another matrix:

$$\begin{bmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

If the result is nonzero, then the flipped bit is given by the number of the correction matrix row that matches the 3-bit result. More details can be found in Trappe and Washington (2002).

DATA COMPRESSION

Signal Compression

It is usually desirable to remove redundant information from a signal by reducing its entropy. Furthermore, this is somewhat surprisingly most often realizable—within limits. It is useful to remove entropy from each specific signal according to its particular nature. The entropy of a particular kind of signal determines the degree of compressibility. If it is then needed to compensate for noisy channels, one can apply common, standardized, signal-independent methods to include required data-integrity checks transmitted along with the compressed signal packets. Compression algorithms may be either lossless or lossy. Lossy compression algorithms reduce entropy by removing information, which cannot later be restored. This feature is tolerated in many cases of interest when it is deemed that the excised information content is less important for the specific method of using the signal.

Arguably one of the earliest “modern” digital, lossless, compression algorithms is Morse code, a type of pulse-width modulation (see Figure 10). To spare human operators from digital carpal tunnel syndrome and improve the efficiency of transmitting coded messages over telegraph wires, a symbol table or dictionary was devised. This technology predated the invention of analog telephones. Of course, now we have come full circle and use digital telephony. In general terms, a *dictionary data structure* is a mapping between an input key and an output value. Morse code maps a letter of the printable alphabetical characters (ASCII codes 0×20 through 0×76) to a pulse-width pattern. It improves efficiency, at least to a first-order approximation, by using the smallest code for the most commonly used letter in the English language and, conversely, using a longer code for least probably used letters or other characters. This can be seen for the letters given in Figure 10.

Note that there must be a pause (greater than one long pulse width) between symbols transmitted to avoid confusion during decoding. Below we will examine ways of

Figure 10: Morse codes

removing the long pause while retaining the unique decoding of the transmitted message.

Early in the twentieth century, telephone transmissions relied on analog basebanded AC signals with a bandwidth from a few decahertz to kilohertz. This has been dubbed plain old telephone system (POTS). An important feature of this system was the need for switching a dedicated channel to allow one or more (“party line”) customers to tie up a circuit. This system morphed into the public telephone switched network (PTSN). During this time, the nature of the signals were analog on the transmitting and receiving end but converted into digital packets between switching centers. The first “crossbar switches” were literally bars of copper that were moved by electromagnetic relays with a deafening racket. Later, of course, solid state digital circuitry replaced the relay arrays. The digital channel supported a signal with a bandwidth of 64 kbits/sec.

An interesting type of signal compression used was named *compansion*. This is a nonlinear compression algorithm. In North America, the particular algorithm used is called μ -law. A similar algorithm called A-law is used in Europe. Because human auditory perception is inherently nonlinear, it was realized that digital channel bandwidth could be effectively reduced, with little noticeable degradation in perceived quality, by nonlinear compression at the transmitter, followed by the inverse nonlinear expansion at the receiver. Although this compression algorithm is invertible, it is (somewhat) lossy when applied to signals in the digital domain. One can discretely sample human speech using a twelve-bit nonlinear ADC, producing an eight-bit output word. Then one can compress and expand using the μ -law relations

$$y = f(x) = \text{sgn}(x) \frac{\ln(1 + \mu|x|)}{\ln(1 + \mu)}$$

and

$$x = f^{-1}(y) = \text{sgn}(y) \frac{1}{\mu} \left\{ (1 + \mu)^{|y|} - 1 \right\}$$

where $\mu = 255$, and the normalized signal lies within the range $-1 \leq x, y \leq +1$.

Huffman Codes

A Huffman code is a type of more complicated offspring, resulting from marriage between run-length encoding and the concept of Morse code. It is a lossless compression algorithm that uses a dictionary. Run-length encoding relies on multiple sequential occurrences of symbols. Instead of transmitting each symbol n times, it transmits a pair {symbol code, count}. Obviously, if multiple occurrences of each symbol are rare, then there may be expansion rather than compression. Run-length coding might be useful for sparse occurrences of symbols above a more prevalent and constant background field. Furthermore, run-length coding has no overhead resulting from output symbol delays. Morse code uses a single fixed-length symbol as input to its dictionary but achieves compression

efficiency by adjusting the dictionary according to the probability of occurrence of each key. Yet it suffers from output symbol delays.

A Huffman code employs a dictionary but constructs the keys as symbol groups. It also adjusts the dictionary structure so that more commonly occurring input symbol groups yield smaller output symbol sizes. There is no extra delay between transmission of output symbols. Usually, a Huffman algorithm first scans (possibly several times) a test signal stream segment so that it can build the weighted dictionary. Then the dictionary is subsequently used without further modification. Of course, if the input signal is quasi-stationary and has lower bandwidth than that of the digital processor implementing the Huffman coder, one could periodically rebuild the dictionary. In any case, the dictionary structure must be transmitted along with the output data stream to allow successful decoding at the receiver.

A Huffman dictionary is constructed by building a binary tree data structure, after scanning the test input data chunk, and storing probabilities of occurrence for successively more complicated symbol groups and stopping at some predetermined upper limit to the multisymbol group size. Next, it builds the dictionary binary tree by starting with the most complex (largest) multisymbol group, then keeps bifurcating as it successively prunes the size of multisymbol groups. As it bifurcates from the root of the tree, the least probable daughter symbol group, called a *terminal leaf node*, is assigned a 0 bit. The more probable daughter is awarded a 1 bit and allowed to continue to bifurcate.

Consider the following example, which is similar to the example discussed in Trappe and Washington (2002). Suppose we have four symbols—denoted A, B, C, and D—that occur with probabilities 0.5, 0.1, 0.3, and 0.1, respectively. We can construct the Huffman code as follows. First, the symbols are listed in descending probability. Because B and D are equally probable, these two symbols can be listed in either order. The procedure that follows is illustrated in Figure 11.

The actual codes are read from right to left in Figure 10 so that the code for A is 1, the code for C is 01, the code for B is 001, and the code for D is 000. More

Figure 11: Huffman coding

information can be found in Press et al. (1992) and Trappe and Washington (2002).

JPEG Compression

JPEG is an acronym for Joint Photographic Experts Group. This committee produced a document that outlined specifications for lossy compression of single image frames. Specific implementation details were left open to designers as long as they complied with the standards. Nevertheless, a single, specific implementation structure quickly gelled and is in common usage.

The human visual system has some peculiarities, in that it perceives certain features of the visual field much better than other features. For instance, the human retina has far more sensors (rods), which perceive gray-scale levels, than it has color sensors (cones). Furthermore, the rods are more sensitive than the cones and are positioned more favorably in order to sample the incoming light. The JPEG algorithm allocates only half as many sampled bits to the red- and blue-like natures of the signal than it does to the gray-scale nature. This provides an immediate compression factor of 75 percent, at least for color images. This technique was discovered in the early part of the twentieth century and implemented in the unequal allocation of television bandwidth to color versus gray scale.

The eye is also more sensitive to low-scale frequencies than to high-scale frequencies. For instance, the eye better perceives the large rectangles of solid color of a Mondrian painting than it does the finely divided, alternating lines and spaces of a mesh screen. The space of scale frequency has two dimensions because it corresponds to the two-dimensional FFT (actually, discrete cosine transform, or DCT) of the two-dimensional light-intensity input. Fourier transforms of two-dimensional data frames are extremely costly in computational overhead. One must first transform each row and then again each column in turn. Without the speedup that the FFT provides, this would computationally cost $O(M^2N^2)$ for a frame with M rows by

N columns. Using FFT techniques, this can be reduced to $O(MN\log_2(M + N))$, a vast improvement.

In addition, a great deal of study has been undertaken to determine the most optimal type of transform to employ, specifically well tailored to human visual perception. Nominally, the best choice was a DCT. The cosine function is even under reflection about the abscissa origin. This property assists in smoothly matching inter-frame boundaries. The entire visual frame is subdivided into eight-by-eight pixel blocks. The DCT is applied independently to each block. Thus, because this is a boxcar window, there are noticeable “ringing artifacts” at block boundaries, especially at high compression ratios.

After the DCT has been applied, the resulting transform amplitudes are weighted such that low-scale frequencies receive higher weights, while high-scale frequencies receive lower weights. This is how the main signal compression is done.

Finally, the compressed signal is Huffman coded, affording additional modest compression. More information can be found in Beauchamp (1984), Pennebaker and Mitchell (1992), and Pratt (2001).

Figure 12 illustrates typical compression (8×) and extremely tight compression (32×). Notice that the tightly compressed image has “blocky artifacts” near regions of sharply changing luminance.

MPEG

MPEG is an acronym for Motion Picture Experts Group. It is a committee for outlining specifications for streams of synchronization time codes, image frame components, and audio frames. The image frames, and audio frames, are separately compressed in a lossy fashion. The algorithms for video compression are quite different from the algorithms used to compress audio. However, both classes of algorithms exploit nuances of the human perceptual system. Specific implementation details are left open to designers, as long as they comply with the standards. Refer to the preceding section on JPEG compression for

Figure 12: JPEG compression; 8× (left), 32× (right)

more details concerning lossy compression of still image frames.

The MPEG standards are an extremely complicated and evolving hierarchy of modes. Major milestones in this hierarchy have been designated MPEG-1, MPEG-2, and MPEG-4. Note carefully that the numerical suffix does not in fact indicate improvements achieved during a historical timeline. Instead, each of these three standards regimes specifies general restrictions on bandwidth and classification of the compression algorithms. More information can be found in Mitchell et al. (1996) and Pratt (2001).

Text documents can usually be compressed, in a lossless fashion, by at least a factor of two, using variants of the commonly exploited ZIP/GZIP archival software. This class of software uses lossless compression algorithms, pioneered by Abraham Lempel, Jacob Ziv, and Terry Welch (LZW) in the early 1980s. Audio and video streams do not compress well using the LZW algorithms. Instead, newer classes of perceptual-based compression algorithms were developed.

In this chapter, we do not outline the rich history in the development of audio or video compression techniques. Before MPEG, midrange hardware modules and software applications assembled sequences of still frames. Each frame was processed using a variant of DCT/JPEG compression. This method was often labeled “motion JPEG.” Each manufacturer developed proprietary, and mostly noninteroperable, methods and storage formats.

Unlike motion JPEG, MPEG video compression performs interframe tracking. This mechanism incorporates three types of image frames: I, P, and B. The intracoded frames are anchors, encoded by JPEG, without reference to other image frames. The *predictive* frames track changes between earlier I and P frames. The *bidirectionally predictive* frames track changes between earlier and upcoming I or P frames. The block-based *motion tracking* determines a group of most probable block motion vectors. In image regions where block tracking fails, the JPEG algorithm is used by default. The compression ratio is usually enhanced over that of motion JPEG at the cost of additional complexity in the algorithm.

OTHER TOPICS

Here we briefly mention two interesting alternative coding transforms. The first, the *Walsh transform*, is specially designed for processing digital pulse trains rather than sinusoids. The second, the *wavelet transform*, is a recursive, self-similar transform. It is specially designed for processing a signal type that lies between a pure time-domain representation, and a pure frequency-domain representation. Each transform type in turn is extremely powerful for manipulating its specialized signal representations. These representations may seem rare compared to the better-known sinusoids but have risen in importance in the past several decades.

Walsh Transforms

Most signals in the analog domain can be described efficiently by a truncated Fourier series with a finite number

Figure 13: Walsh transform basis functions

of terms. For sequences of pulses (pulse trains) such as Morse-coded streams, the sharp discontinuities are not well represented by smoothly varying sinusoids. Thus, the Fourier transform of rectangular wave signals yields poor results. For somewhat similar reasons, a boxcar-windowed Fourier transform of a sinusoidal signal has certain issues because of the rectangular boxcar window. The Walsh transform domain is analogous to the frequency domain, except that its representation uses only two values for both input and output: -1 , $+1$. The first four Walsh functions, ordered by increasing number of zero crossings, are illustrated in Figure 13.

Both Fourier transforms and Walsh transforms use particular complete sets of orthonormal basis functions. In the case of Fourier transforms, the basis functions are sinusoids. In the case of Walsh functions, the basis functions are rectangular waves of varying width and delay or phase. Both transforms are specific implementations of general abstract number-theoretic transforms. Another implementation, the Hadamard transform, has a domain similar to that of the Walsh domain but uses three values for both input and output: -1 , 0 , $+1$. In some abstract sense, one can think of the Walsh basis as measuring the position and direction of the zero crossings of the Hadamard basis. (This analogy cannot be stretched too far.) Walsh functions are also important in studying *sequency theory* for streams of two-valued numbers.

There are (at least) two main problems with generalized abstract number-theoretic transforms. First, the time and phase (sequency) ordering, and the corresponding transform indexing or duration and rate, are usually not as conceptually straightforward as in the case of the Fourier sinusoid bases. Second, the FFT calculation speedup from $O(N^2)$ to $O(N \log N)$ cannot usually be extended to the case of generalized abstract number-theoretic functions. In specific cases, it can be done, but the performance enhancement is not as significant as in the FFT case. There is, in fact, a fast Walsh transform (FWT), which is not as “fast” as the FFT, but is a significant step in that direction. More information concerning Walsh transforms and sequency theory can be found in Beauchamp (1984).

Figure 14: Wavelet compression; $8\times$ (left), $32\times$ (right)

Wavelet Transforms

In the case of Fourier transforms, the basis functions consist of orthonormal, complex-valued circular functions (sinusoids). These basis functions work well for smoothly varying signals but rather poorly for signals with sharp transitions such as pulse trains. One metric for “working well” often means that the signal can be approximated by truncating the linear series of weighted basis states, using fewer terms. A second important issue is the discrete sampling of continuously changing signals. This reduces the region of periodicity to a finite frequency interval with repeated, or aliased, copies. If the signal was not properly band-limited via filtering before sampling, then one suffers aliasing contamination. This is effectively a “feed-through” between successive band edges.

One can view the finite number of successive terms in the FFT, or DCT, as successive powers of a basis frequency, with different phase shifts. In an abstract sense, it is analogous to starting with one period of a sinusoid, followed by various stretchings (frequency changes), and translations (phase shifts). In the cases of the FFT or DCT, the complementary representations are the time domain versus the frequency domain. However, sometimes we would like to use some representation in between. In other words, we would sacrifice some time localization for better simultaneous frequency localization and conversely. The wavelet transforms provide just such a mixed worldview.

The wavelet transforms, pioneered by Ingrid Daubechies, start with an abstract base wavelet and then perform stretches and shifts on this base wavelet, summing all the (weighted) pieces. However, the input data stream must first be buffered into a large frame (such as an entire image frame) as opposed to smaller chunks (such as an eight-by-eight pixel subframe). Then that full frame buffer must be rescanned several times during the operation of the wavelet transform. More information can be found in Daubechies (1992), Meyer (1993), and Strang and Nguyen (1996).

Here we consider a specific application of wavelets, namely, still image frame compression, as in the JPEG-2000 specification. Even though it is now 2007, and wavelet compression methods have been in (limited) use since the early 1990s, JPEG-2000 remains largely unused. As one increases the usual JPEG compression factor to large values, one clearly notices the visually unpleasant artifacts near edges of rapid contrast change. An example is a light-colored garment in front of a dark background field. This is commonly observed in newspaper photos broadcast by satellite channels with limited bandwidth. In the case of wavelets, as the compression factor increases, instead of diffraction anomalies at edges, one notices instead a soft blurring of the resultant still image frame. More information can be found in Strang and Nguyen (1996).

Wavelet compression of still image frames uses other important features in addition to the wavelet bases. A popular implementation employs a pair of matched quadrature mirror filters using seven-tap and nine-tap FIR linear phase filters. Figure 14 illustrates modest compression ($8\times$) and tight compression ($32\times$). Notice that the tightly compressed image has blurred softly in contrast to the case of standard JPEG compression illustrated in Figure 12. The “blocky artifacts” have been smoothed out.

CONCLUSION

In this chapter, we first presented details regarding Shannon’s theory, which formulates a concise methodology for describing the information content of data transferred between different locations. In particular, the theory considers characteristics of the communications channel, including data content, signal transducers, channel capacity, noise and error rate, and ultimately the integrity of data at the receiver. An important measure of the data is information redundancy. Shannon developed a metric for data redundancy, which he named *entropy*, and which is analogous to the concept in thermodynamics and statistical mechanics. The data transfer rate

depends critically on channel capacity and integrity. Low channel capacity can be mitigated by careful removal of information redundancy—that is, by data compression. Conversely, noisy channels can be mitigated by increasing the size of the data by adding redundancy codes.

The rest of the chapter presented a brief introduction to digital signal processing, integrity of transferred data, and data compression. Digital coding and data transfer permit significant improvements over older analog technology. These improvements include enhanced data transfer reliability, lower overall cost, superiority in modular design and implementation, and more efficient use of available channel bandwidth.

The signal processing introduction comprised general and specific topics. We discussed digital sampling of signals and important methods to overcome some fundamental issues. The sampling rate is a crucial factor, which must be carefully matched to the bandwidth of the data. The data must first be prefiltered or oversampled to avoid corruption in the frequency domain. These considerations lead to techniques for expressing data content in the time and frequency domains. Mathematical methods for relating these two domains mainly use integral transforms in the analog regime, and their discrete expression in the digital regime. An important method uses the Fourier transform, which permits significant speed advantages because of work by Cooley, Tukey, and earlier researchers.

The rest of the article presents a brief introduction to several specialized topics, illustrating current techniques to enhance data transfer reliability and eliminate data redundancy.

GLOSSARY

Coding theory: The science of transmitting data over a channel in such a way that errors can be detected and, in some cases, automatically corrected at the receiving end. This is distinct from source coding, where the goal is to compress the data (see Huffman coding below).

Cyclic redundancy code (CRC): An error-detecting code that is computed by long division, with the remainder being the CRC value. These codes are particularly good at detecting burst errors.

Discrete cosine transform (DCT): A mathematical operator that transforms an image from the pixel amplitude space into the scale frequency space (and vice-versa), using a basis consisting of orthogonal cosine functions.

Entropy: In information theory, a measure of the amount of randomness or uncertainty. In communication systems, entropy is a fundamental concept related to error-correcting codes, data compression, and so on.

Fast Fourier transform (FFT): A recursive mathematical method that significantly speeds up a Fourier transform.

Fourier transform: A method for writing a function in terms of sinusoidal functions of various frequencies. The Fourier transform is used to convert between the *time domain* and *frequency domain* representations of a function.

Gray code: A method of listing binary n -tuples so that successive terms differ in exactly one bit position.

Hamming code: An error-correcting code that can detect all one- and two-bit errors and can correct all one-bit errors per block. A *block* consists of seven bits, where four bits are data.

Hash function: A function in which the output *summarizes* the input data. Typically, such functions compress an arbitrary size input to a fixed size output, with the output acting as a fingerprint of the data. One use for such functions is to detect errors in the input data by comparing the hash value to a previously computed hash value. Cryptographic hash functions are a special class of such functions that are resistant to intelligent attacks, as opposed to simply detecting random errors.

Huffman coding: A lossless form of data compression that uses probabilistic information about the data so that the more common symbols are represented with fewer bits than the less common symbols.

Information theory: The mathematical theory of communication founded by Claude Shannon in 1948.

JPEG: A lossy form of compressing images.

MPEG: A lossy compression method for video.

Nyquist rate: The minimum sampling rate that can be used so that the signal can be reconstructed from the samples. The Nyquist rate is twice the highest frequency that the signal contains.

Run length encoding (RLE): A simple *compression* method whereby a string of repeated symbols is replaced by one copy of the symbol and its run length. For example, AAAAAAAAAA could be replaced by 10 A. In many cases, this approach will greatly compress the data, but in some cases it can actually expand the data.

Walsh transform: A generalized Fourier transform that, like the Fourier transform, can be implemented efficiently.

Wavelet transform: A transform technique that is an alternative to the Fourier transform.

Windowing: A function that is zero outside of some “window” or range. When data are multiplied by such a function, they are then also zero outside of the window. Such a window can be used, for example, to restrict the Fourier transform to a particular time interval.

INTRODUCTION

Rapid advances in computing and communication technologies support lifestyles in the information age, which features an increasing demand for a wide range of multimedia services, including voice, audio, and video services. Multimedia data, however, require a huge amount of storage space or high transmission bandwidth. There are two approaches to support multimedia services. One increases the capacity of storage devices and transmission channels, and the other compresses data compactly, thereby exploiting existing system capacity. System capacity has increased continuously, but the need for more storage space and higher bandwidth is increasing at an even faster pace. Moreover, new types of multimedia data are emerging. Therefore, extensive efforts have been made to develop data compression techniques to use limited storage space and bandwidth effectively.

Data compression is ubiquitous in our daily lives, and its application list is extensive. For example, it would take a much longer time to browse Web sites on the Internet that contain audiovisual information if there were no data compression techniques. Data compression enables us to send photographs or music files efficiently via e-mail. Also, digital TV broadcasting, real-time video streaming, and the storage of high-quality video on digital versatile disc (DVD) are possible because of video compression technology, which compresses a huge amount of video data efficiently. Recently, mobile communications have become popular, and there is an explosive demand for mobile multimedia services such as wireless Internet, mobile commerce (m-commerce), and game services. Data compression is one of the key technologies that enable the transmission of multimedia data as well as voice over bandwidth-limited wireless channels.

Data compression can be classified into two categories (Witten, Moffat, and Bell 1999): lossless and lossy techniques. In *lossless compression*, an encoder compresses the source data in such a way that the decoder can reconstruct the original data exactly from the compressed data. The lossless property is essential in some applications, such as the compression of texts, medical imaging, and

satellite imaging for remote sensing, where even small changes in data may lead to undesirable results. Also, lossless compression techniques are used to archive numerous types of data without loss of information.

In contrast, *lossy compression* attempts to achieve better compression by allowing loss of information during the compression procedure. There is a trade-off between the accuracy of reconstructed data and the compression performance. Audio and video data are usually compressed in a lossy way because the human perceptual system can tolerate a modest loss of audiovisual information. Moreover, audio and video data require much larger storage spaces than text. For example, consider a video clip with a frame rate of 15 frames/sec. If each frame consists of 176×144 pixels and the color information of each pixel is represented with 24 bits, then the video clip requires the transmission bandwidth of about 9 Mbps. Suppose we want to transmit the clip over a 56-Kbps modem. The compression performance is often measured by the compression ratio, defined by

$$\text{Original data size/Compressed data size}$$

In this case, we need a very high compression ratio, approximately 160 (= 9 Mbps/56 Kbps), and thus it is reasonable to select lossy compression techniques.

In 1948, Shannon established the field of information theory (Shannon 1948), which measures the amount of information in data quantitatively. Since the late 1960s, the subject of data compression has undergone extensive study, and numerous concepts and algorithms have been developed. In this chapter, we survey lossless and lossy compression techniques and exemplify their application areas.

LOSSLESS COMPRESSION

In lossless compression, an exact duplicate of the original data can be reproduced after the compression and decompression procedures. We introduce several concepts and tools for lossless compression in this section.

Table 1: Examples of Codes

Symbol	Probability	Code 1	Code 2	Code 3	Code 4
A	0.5	0	0	0	11
B	0.25	1	10	01	0
C	0.25	10	11	11	10
Average length		1.25	1.5	1.5	1.75

Examples of Codes

In most digital computers, data are represented by binary numbers. Also, data are converted into binary numbers before transmission over digital communication channels. Data *compression* or *coding* refers to the mechanism of assigning binary strings to samples of a data source in a compact way. The set of binary strings is called a *code*, and each string is called a *code word*.

Suppose that a communication system transmits a sequence of symbols (or samples) selected from an alphabet $\{A, B, C\}$ and that the probabilities of the symbols are given by

$$p(A) = 0.5, p(B) = 0.25, p(C) = 0.25 \quad (1)$$

Table 1 shows four codes for this alphabet. The average length of a code is defined by

$$L = p(A)l(A) + p(B)l(B) + p(C)l(C)$$

where $l(A)$, $l(B)$, and $l(C)$ are the numbers of bits assigned to symbols A , B , and C , respectively. Code 1 seems to be most efficient because it requires the least number of bits to transmit each sample on the average, but it cannot be used in communication systems because more than two sequences of samples can yield the same binary sequence. Let us assume that the decoder receives the binary sequence 10. Both C and BA are encoded into the same sequence 10. Therefore, the decoder cannot determine whether it is generated by C or BA . To avoid this ambiguity, a code should be uniquely decodable—that is, every distinct sequence of samples should be mapped into a different binary sequence.

Code 2 is a uniquely decodable code. A code is called a *prefix code* if no code word is a prefix of any other code word. Therefore, code 2 is also a prefix code. Figure 1(a) is the tree representation of code 2. Each code word is a

leaf node, because code 2 is a prefix code. Therefore, every binary sequence can be deciphered without ambiguity by traversing the tree. Let us decode 01110. Starting from the *root node*, the decoder traverses to the left child if the input bit is 0 and to the right child otherwise. When the decoder meets a leaf node, it outputs the corresponding symbol and starts again from the root node. Thus, 01110 can be deciphered into 0 11 10 = ACB . Note that every prefix code is a uniquely decodable code, and each code word in a prefix code can be decoded instantaneously without reference to future code words.

However, not every uniquely decodable code is a prefix code. Code 3 is a uniquely decodable code but not a prefix code. Figure 1(b) shows its tree representation. The code word for A lies on the path from the root node to the code word for B , because 0 is a prefix of 01. Therefore, when the decoder meets 0, it needs to check future bits to properly decode symbols. When 0 is followed by an even number of 1's, it is decoded into A . Otherwise, it is decoded into B . For example, 011110111 is decoded into 0 11 11 01 11 = $ACCB$. In the worst case that a binary sequence is a concatenation of a single 0 and an infinite number of 1's, the code 3 decoder need check infinitely many future bits to decode the first sample. The decoding of a nonprefix code hence may incur an unbounded delay and is more complex than that of a prefix code.

The goal of code design is to find an optimal uniquely decodable code that provides the minimum average length. It can be shown (Cover and Thomas 1991) that the minimum average length can be achieved also by a prefix code. Therefore, we can restrict our attention only to the set of prefix codes, which are instantaneously decodable. Code 2 actually achieves the minimum average length. Code 4 is also a prefix code, but less efficient than code 2. It assigns a longer code word to the symbol A than the symbol B , although A is more probable than B . It is readily seen that an efficient code should assign longer code words to less probable symbols.

Figure 1: Tree representations of (a) code 2 and (b) code 3 in Table

Entropy

In 1948, Shannon published “A Mathematical Theory of Communication,” which founded the field of information theory. He developed a set of concepts that are necessary to understand the process of communication quantitatively. One concept is *entropy*, which measures the amount of information or uncertainty in a data source. More specifically, the entropy of a data source is the number of bits required on the average to describe a sample of the data source. The entropy depends only on the probability

distribution of symbols and has nothing to do with what the data represent.

As mentioned previously, an efficient code should assign longer code words to less probable symbols. Thus, the information or uncertainty of a symbol should be defined to be inversely proportional to its probability p . To find an adequate inversely proportional function, let us consider an alphabet that consists of sixteen equiprobable symbols. Because the symbols have the same probability ($1/16$), they should be assigned code words of the same length. Obviously, the optimal code consists of the four-bit binary representations of decimal numbers 0–15:

```
00000001 00100011 01000101 01100111
10001001 10101011 11001101 11101111
```

Hence, a symbol of probability $1/16$ has four-bit uncertainty. Similarly, considering an alphabet that consists of 2^n equiprobable symbols, it can be seen that a symbol of probability $1/2^n$ has n -bit uncertainty. In general, a symbol of probability p has $\log_2(1/p)$ -bit uncertainty. Note that $\log_2(1/(1/2^n)) = \log_2 2^n = n$.

Consider a random data source X consisting of n symbols, which have probabilities p_1, p_2, \dots, p_n . The entropy $H(X)$ of the data source is the average uncertainty of the symbols and thus given by

$$H(X) = \sum_{i=1}^n p_i \log_2 \frac{1}{p_i} \quad (2)$$

This derivation of entropy is oversimplified. The entropy can be derived rigorously from three axioms (Shannon 1948). Moreover, the entropy has the profound meaning that at least $H(X)$ bits/sample are required to encode a data source X losslessly, no matter what compression scheme is employed. In other words, $H(X)$ is the fundamental lower bound for the average length that a code can achieve. For example, the entropy of the alphabet in Table 1 is

$$0.5 \log_2 \frac{1}{0.5} + 0.25 \log_2 \frac{1}{0.25} + 0.25 \log_2 \frac{1}{0.25} = 1.5$$

Therefore, no code can achieve less than 1.5 bits/sample on the average, which is the average length of code 2 in Table 1.

Huffman Coding

Huffman coding constructs an optimal prefix code that provides the minimum average length (Huffman 1952). It is based on the observation that the optimal code should allocate longer code words to less probable symbols. Let us consider a random data source with n symbols. Without loss of generality, we assume that

$$p_1 \leq p_2 \leq \dots \leq p_{n-1} \leq p_n$$

where p_i denotes the probability of the i th symbol. Then the code word lengths should satisfy

$$l_1 \geq l_2 \geq \dots \geq l_{n-1} \geq l_n$$

Figure 2: Construction of a Huffman code

where l_i is the code word length of the i th symbol. Note that if $l_1 > l_2$, then the last $(l_1 - l_2)$ bits of the longest code word can be trimmed without violating the prefix condition. In other words, the code is not optimal. Hence, l_1 should be equal to l_2 . Moreover, the optimal code can be designed such that the two longest code words should differ only in the last bit.

As shown in Figure 1(a), a prefix code can be represented by a binary tree. The above observations mean that the two least probable symbols should correspond to the two deepest nodes in the tree, and the two nodes should be siblings. Therefore, we can construct the optimal tree using a bottom-up method. Figure 2 illustrates how to construct a Huffman code. First, we merge two least probable symbols, while assigning 0 and 1 to the last bits of the corresponding code words. The merged node is treated as a new symbol with the probability 0.1, which is the sum of the two child node probabilities. Second, we find again two least probable symbols. There are three symbols with the probability 0.1 at this stage. We arbitrarily merge two symbols among the three symbols into a new symbol and assign the probability 0.2 to the merged symbol. Proceeding in this way, we can merge all nodes into the root node. Then the original symbols are assigned the code words, which are the top-down concatenations of branch bits.

It can be shown (Cover and Thomas 1991, Chapter 5) that the average length $L(X)$ of the Huffman code for a random data source X satisfies

$$H(X) = L(X) < H(X) + 1 \quad (3)$$

For example, the entropy of the probability distribution in Figure 2 is 2.0872, whereas the Huffman code achieves the average length 2.15. $L(X) = H(X)$ if and only if the probability of each symbol is dyadic—that is, equal to 2^{-k} for some non-negative integer k .

The upper bound in equation 3 indicates that the Huffman coding scheme introduces at most one bit of over-head as compared to the entropy. This overhead may cause a problem in some situations. Suppose that a communication system transmits samples selected from an alphabet $\{A, B\}$, and $p(A) = 0.99$ and $p(B) = 0.01$. The entropy of the alphabet is 0.0808. But, as shown in $p(A)$ in the left column of Table 2, the Huffman code requires 1 bit/sample on the average, which is approximately twelve times higher than the entropy. We can reduce the overhead by encoding n consecutive samples simultaneously. In the middle column of Table 2, two consecutive samples are grouped into a block, and the Huffman code is constructed for the set of possible blocks. The Huffman code introduces at most 1 bit overhead per block, hence

Table 2: Huffman Coding of Grouped Samples

No grouping			Grouping of 2 samples			Grouping of 3 samples		
Symbol	Probability	Code	Block	Probability	Code	Block	Probability	Code
A	0.99	0	AA	0.9801	0	AAA	0.970299	0
B	0.01	1	AB	0.0099	10	AAB	0.009801	100
			BA	0.0099	110	ABA	0.009801	101
			BB	0.0001	111	ABB	0.000099	11100
						BAA	0.009801	110
						BAB	0.000099	11101
						BBA	0.000099	11110
						BBB	0.000001	11111
Average bits/sample = 1			Average bits/block = 1.0299			Average bits/block = 1.06		
			Average bits/sample = 0.515			Average bits/sample = 0.3533		

at most 1/2 bit overhead per sample. In general, if we design the Huffman code for n -sample blocks, it incurs only $1/n$ bit overhead per sample. Therefore, by increasing n , we can achieve an average bits/sample arbitrarily close to the entropy, which is the theoretical lower bound.

Arithmetic Coding

Huffman coding may require the grouping of more and more samples to achieve an average bits/sample that is arbitrarily close to the entropy. However, the grouping of samples introduces transmission delay and requires a higher computational load and a larger storage space for the code word table. Arithmetic coding is an alternative coding scheme that provides a near-optimal compression performance without requiring the grouping of samples. It treats a whole sequence of samples, called a *message*, as a single unit, but can be implemented to generate output code words incrementally as samples arrive (Bell, Cleary, and Witten 1990).

In arithmetic coding, a message is mapped to an interval of real numbers between 0 and 1. The interval length is proportional to the probability of the message, and any number in the interval can be used to represent the message. Less probable messages yield longer sequences of bits, while more probable messages yield shorter sequences.

For example, suppose that the alphabet is $\{A, B, C\}$, and the symbol probabilities are $p(A) = 0.6$, $p(B) = 0.3$, and $p(C) = 0.1$. In Figure 3, the messages starting with A , B , and C are respectively mapped to the half-open intervals $[0, 0.6)$, $[0.6, 0.9)$, and $[0.9, 1)$, according to their probabilities. Let us encode a message BCA . Because it starts with B , it is first mapped to the interval $[0.6, 0.9)$. Then the interval is divided into three subintervals— $[0.6, 0.78)$, $[0.78, 0.87)$, and $[0.87, 0.9)$ —that correspond to the messages starting with BA , BB , and BC , respectively. Note that the length ratio of the subintervals is set to

$$0.18 : 0.09 : 0.03 = 6 : 3 : 1 = p(A) : p(B) : p(C)$$

**Figure 3:** Illustration of arithmetic coding

and 0.18, 0.09, and 0.03 are the probabilities of the messages starting with BA , BB , and BC , respectively. Similarly, $[0.87, 0.9)$ is further divided into three subintervals, and the messages starting with BCA are mapped to $[0.87, 0.888)$.

The two end points can be written in binary numbers as

$$0.87 = \frac{1}{2} + \frac{1}{2^2} + \frac{1}{2^4} + \frac{1}{2^5} + \dots = 0.11011\dots$$

$$0.888 = \frac{1}{2} + \frac{1}{2^2} + \frac{1}{2^3} + \frac{1}{2^7} + \dots = 0.11100\dots$$

The prefix “0.” can be omitted because every number within the unit interval $[0, 1)$ is less than 1. Therefore, the interval $[0.87, 0.888)$ can be represented in the binary form $[11011\dots, 11100\dots)$. The encoder can transmit an arbitrary number within this interval to specify that the message starts with BCA . For example, it can transmit the sequence of three bits, 111, which corresponds to 0.875 in decimal. Then the decoder can follow the same division procedure in Figure 3 and know that 0.875 lies within the interval $[0.87, 0.888)$, hence the message starts with BCA .

However, the decoder cannot determine when the message ends. Because 0.875 lies also within the interval $[0.87, 0.8808)$ that corresponds to the set of messages

starting with *BCAA*, it can also represent the message *BCAA*. To make the arithmetic code uniquely decodable, we can add a special symbol to the alphabet that indicates the termination of a message. If the special symbol is assigned a small probability and a message is long, then the addition of the special symbol leads to only a minor degradation in the compression performance.

Arithmetic coding is superior to Huffman coding in many respects. It can achieve a near-optimal performance without grouping samples. Also, it can be easily used in an adaptive way. In some applications, the probability distribution of alphabets cannot be predetermined and should be trained and updated based on the statistics of the data stream itself. To be adaptive to the change in the probability distribution, Huffman coding should regenerate the code word table (Gallager 1978), which is computationally inefficient. In contrast, arithmetic coding can adjust itself to the updated probability distribution simply by changing the lengths of intervals in the division procedure.

Dictionary Coding

Both Huffman coding and arithmetic coding assume that a data source generates a sequence of independent samples and do not consider the dependence between samples. However, samples are dependent on one another in many data sources. For example, consider the following words from a text source:

Inte*net, com*ter, n*two*ks, d*ta, compre*sion

where * denotes a missing letter. We can reasonably recover the words as

Internet, computer, networks, data, compression

based on our knowledge of frequently used words. In other words, the missing letters can be retrieved by exploiting the dependence between letters—that is, by the context.

Dictionary coding achieves data compression by replacing blocks of consecutive samples with indices into a dictionary (Bell, Cleary, and Witten 1990, Chapter 8). The dictionary should be designed to contain symbol blocks that are frequently used. If sufficient prior knowledge of a particular data source is unavailable, then the dictionary can be built adaptively from the source itself. Many adaptive dictionary coding schemes are modifications of one of two approaches, *Lempel-Ziv coding 1977* (LZ77) and *Lempel-Ziv coding 1978* (LZ78) (Ziv and Lempel 1977, 1998). Popular file compression tools such as ZIP and ARJ are variations of LZ77. LZW is one of the most popular modifications of LZ78 and is used in the UNIX command “compress,” the V.42 bis standard for data compression over modem, and the *graphics interchange format* (GIF) for compressing graphical images.

Let us describe the encoding and decoding procedures of LZW. The encoder parses an input sequence into non-overlapping symbol blocks in a dictionary and represents each block with its index to the dictionary. The blocks in the dictionary are also referred to as the *words*. The

Table 3: Dictionary Construction in LZW Coding with Input Sequence *ABABABBBBA*

Index	Dictionary	Comment
1	<i>A</i>	initial
2	<i>B</i>	dictionary
3	<i>AB</i>	(<i>A</i>) + <i>B</i>
4	<i>BA</i>	(<i>B</i>) + <i>A</i>
5	<i>ABA</i>	(<i>AB</i>) + <i>A</i>
6	<i>ABB</i>	(<i>AB</i>) + <i>B</i>
7	<i>BB</i>	(<i>B</i>) + <i>B</i>
8	<i>BBA</i>	(<i>BB</i>) + <i>B</i>

dictionary is initialized with the single symbols in the alphabet and grows during the encoding. Suppose that the alphabet is $\{A, B\}$, and an input sequence is given by

ABABABBBBA

The encoder first parses the longest word in the dictionary from the input sequence. As shown in Table 3, the initial dictionary contains two words, *A* and *B*. Thus, the longest word is *A* and is represented by the index 1. Then it is concatenated with the next sample *B* to form a new word *AB* in the dictionary. Similarly, the next longest word *B* is represented by the index 2, and is concatenated to the next sample *A* to form a new word *BA*. In this way, the input sequence can be parsed into

$$(A)_{AB}(B)_{BA}(AB)_{ABA}(AB)_{ABB}(B)_{BB}(BB)_{BBA}(A) \quad (4)$$

where the parsed words are enclosed in parentheses, and the newly formed words in the dictionary are written as subscripts. Consequently, the input is represented by the index sequence of strings in parentheses in equation 4:

1 2 3 3 2 7 1

The decoder can reconstruct the input sequence from the index sequence by emulating the behavior of the encoder. It also starts with the initial dictionary, consisting of two words, *A* and *B*. Thus, the first index 1 is decoded into *A*, which should be concatenated to the next sample to form a new word in the dictionary. Thus, the decoder looks ahead at the next index 2 that corresponds to a word *B*, and inserts the new word *AB* into the dictionary. Similarly, the decoder reconstructs a word *B* from the second index 2, looks ahead at the next index 3 to find out that the next sample is *A* and inserts a new word *BA* into the dictionary.

Proceeding in this way, the third and fourth indices 3 are decoded into *AB*, respectively, and two new words, *ABA* and *ABB*, are inserted into the dictionary. Then the decoder reconstructs the word *B* from the fifth index 2. The next step is to look ahead at the next index 7 to find out the next sample, denoted by *, and concatenate *B* and * to construct a new word *B** in the dictionary. This requires caution. Note that the index 7 cannot be directly parsed into a word because the dictionary contains only

six words and the seventh word is being constructed at this stage. However, we know that the seventh word starts with B , thus the next sample * is B . Therefore, the seventh word in the dictionary is BB , and the decoder can continue.

Adaptive dictionary coding can be used to compress all types of data, thus being classified as a universal coding scheme. However, care should be taken with its use. It can compress a data source effectively, provided that the source generates frequently recurring patterns or groups of samples. Text data provide a good example. In contrast, dictionary coding is not the most efficient way to compress natural image data, speech, and so on that contain relatively few repetitive patterns. These data can be more effectively compressed by employing other approaches that are described later.

Run-Length Coding

Run-length coding (Jayant and Noll 1984, Chapter 10) is suitable for compressing data that contain large segments of constant sample values. It replaces a sequence of samples by a sequence of pairs, $\{(s_k, r_k)\}$, representing sample values s_k 's and run lengths r_k 's. For example, suppose that an input sequence is given by

AAAABBCCCB BBBB

It starts with a run of A's with length 4, followed by a run of B's with length 2. Thus, the first pair is (A,4) and the second pair is (B,2). Thus, the input sequence is converted into

(A,4), (B,2), (C,3), (B,6)

The sequence of pairs $\{(s_k, r_k)\}$ is usually encoded using the Huffman coding technique.

Run-length coding can effectively compress binary and facsimile images that contain long runs of black (0) and white (1) pixels. Because white and black runs alternate, the colors (or sample values) of runs need not be encoded. To avoid the ambiguity, the color of the first run is assumed to be white, and the white run of length 0 is encoded if the sequence starts with a black pixel. For example, a sequence of pixels

000111110111001

is converted into a sequence of run lengths

0, 3, 5, 1, 3, 2, 1

The decoder can know from the first run length 0 that the sequence starts with a black pixel and interpret the following numbers as the lengths of black and white runs alternately.

LOSSY COMPRESSION

Lossless compression schemes can encode data sources with discrete alphabets only. However, many data sources are analog; that is, their symbols may have arbitrary values from a continuous range of amplitudes.

The lossless description of a continuous sample requires an infinite number of bits. Thus, a finite representation of a continuous sample inevitably incurs some loss of precision; this is called the *quantization error*. Moreover, even if a data source has a discrete alphabet, lossy compression techniques can describe a discrete sample more compactly by allowing some distortion.

In rate-distortion theory (Cover and Thomas 1991, Chapter 13), it was shown theoretically that there is a trade-off relation between the bit rate (in bits/sample) and the distortion. As more distortion is allowed, data can be compressed more compactly. The goal of lossy compression techniques is to minimize the distortion subject to a given bit-rate requirement or, equivalently, to achieve the lowest bit rate subject to a given distortion requirement.

A measure of distortion should be defined in lossy compression techniques. The most common measure is the squared error, defined by

$$d(x, \tilde{x}) = (x - \tilde{x})^2$$

where x is the original sample and \tilde{x} is the reconstructed sample. Also, the mean squared error between two vectors $\mathbf{x} = (x_1, x_2, \dots, x_n)$ and $\tilde{\mathbf{x}} = (\tilde{x}_1, \tilde{x}_2, \dots, \tilde{x}_n)$ is defined by

$$d(\mathbf{x}, \tilde{\mathbf{x}}) = \frac{1}{n} \sum_{i=1}^n (x_i - \tilde{x}_i)^2$$

The squared error distortion is simple to use and has the intuitive meaning that it measures the power of the error signal. Thus, it is used in this section to evaluate the performances of lossy compression techniques.

Scalar Quantization

Quantization is the process of representing a large or infinite set of values with a smaller set (Gersho and Gray 1991, Part II). In scalar quantization, the input and output sets are composed of scalar values. An N -point scalar quantizer partitions the real line into N cells $R_i = \{r : x_{i-1} < r \leq x_i\}$ for $i = 1, 2, \dots, N$, and maps input values within a cell R_i to an output point y_i . Suppose that we have a data source modeled by a random variable X with *probability density function* (Pdf) $f_X(x)$. Then, the quantizer yields the average distortion or the mean squared error given by

$$\begin{aligned} D &= \int_{-\infty}^{\infty} (x - Q(x))^2 f_X(x) dx \\ &= \sum_{i=1}^N \int_{R_i} (x - y_i)^2 f_X(x) dx \end{aligned}$$

where Q denotes the quantizer mapping. Because the quantizer has N output points, each output point can be represented with $\lceil \log_2 N \rceil$ bits, where $\lceil a \rceil$ denotes the smallest integer greater than or equal to a . In other words, the bit rate of the quantizer is given by

$$R = \lceil \log_2 N \rceil (\text{bits/sample})$$

when fixed-length code words are used to encode the output indices.

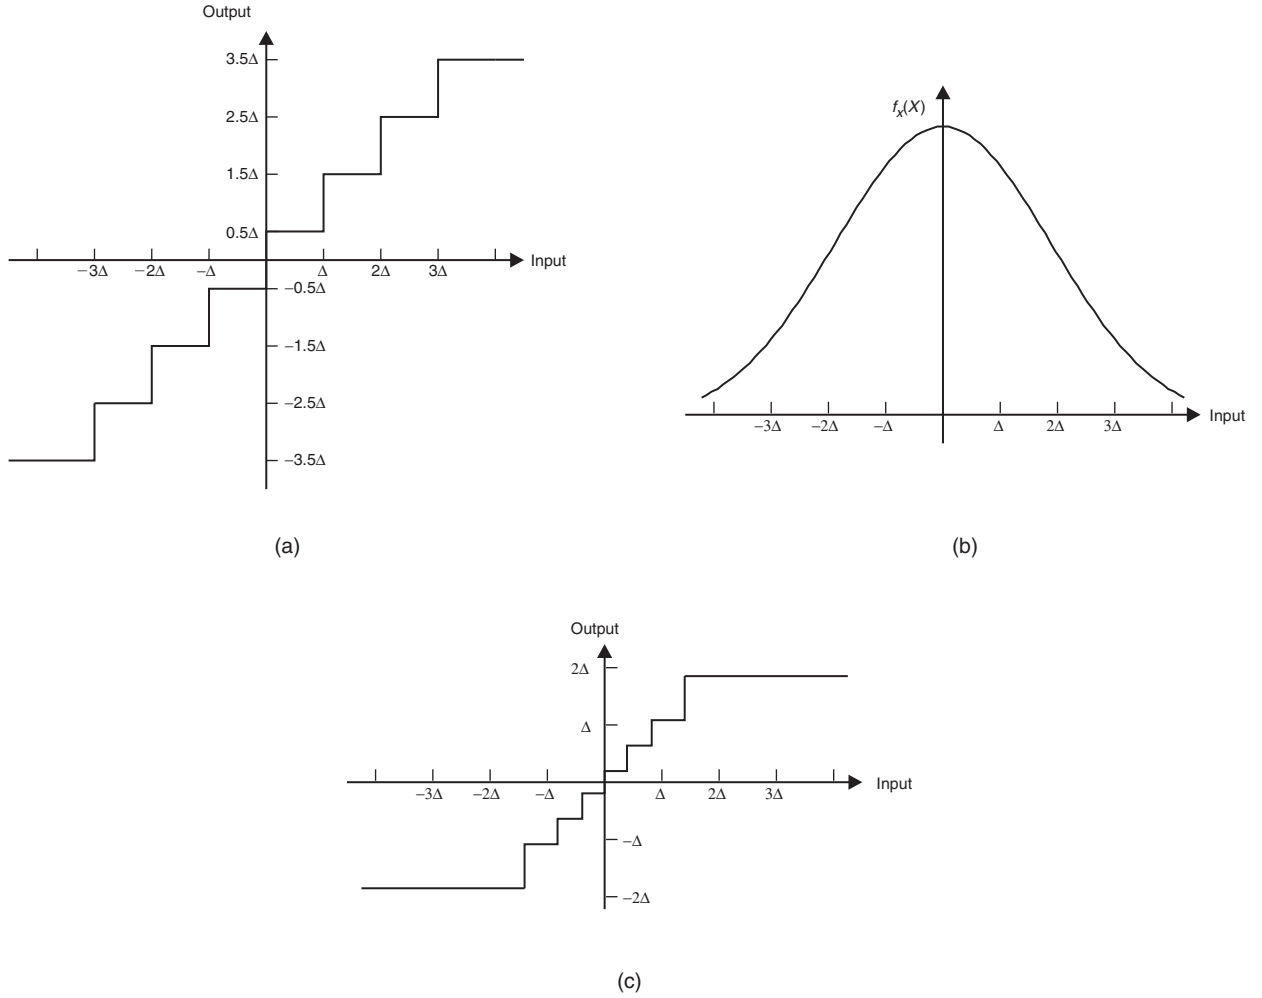

Figure 4: (a) uniform quantizer, (b) Pdf of a random variable, and (c) Lloyd quantizer for Pdf in (b)

For example, Figure 4(a) shows the input-output graph of an eight-point quantizer whose mapping, Q , is given by

$$y = Q(x) = \begin{cases} 3.5\Delta & \text{if } x > 3\Delta, \\ 0.5(2n-1)\Delta & \text{if } (n-1)\Delta < x \leq n\Delta \\ & (n = -2, -1, \dots, 3) \\ -3.5\Delta & \text{if } x \leq -3\Delta. \end{cases}$$

Except for the two outermost cells, every cell has the same length Δ . Thus, it is called a *uniform quantizer*. The bit rate is 3 bits/sample when fixed-length code words are employed, because the quantizer has eight output points. However, output points can be described more compactly because they do not have the same probability. Suppose that a random variable X has a Pdf $f_X(x)$ shown in Figure 4(b). The probability P_i of the i th output point is given by

$$P_i = \int_{R_i} f_X(x) dx \quad (1 \leq i \leq 8)$$

Note that the fourth and fifth output points have higher probabilities than other points. Therefore, entropy coding

schemes such as Huffman coding and arithmetic coding can achieve a higher compression ratio than fixed-length coding by exploiting the nonuniform probability distribution of the output indices.

In practice, for a random variable with a Pdf such as the one shown in Figure 4(b), the uniform quantizer is not the optimal eight-point quantizer that yields the lowest average distortion. Notice that a quantizer can reduce the average distortion by approximating the input more precisely in regions of higher probability. The optimal quantizer should make cell sizes smaller in regions of higher probability.

The Lloyd algorithm (Lloyd 1982) is an iterative method that finds a locally optimal quantizer for a given Pdf, which is based on two sufficient conditions for the optimal quantizer. First, an output point y_i should be the centroid of the corresponding cell R_i ,

$$y_i = \frac{\int_{R_i} x f_X(x) dx}{\int_{R_i} f_X(x) dx} \quad (5)$$

Second, a cell boundary point x_i should be the midpoint between two adjacent output points,

$$x_i = \frac{y_i + y_{i+1}}{2} \quad (6)$$

The Lloyd algorithm first determines output points by equation 5 after fixing boundary points. These output points are then used to select boundary points by equation 6. These two steps are repeatedly applied until the change between the obtained average distortions becomes negligible. Because each step reduces the average distortion, the Lloyd algorithm always converges to a locally optimal quantizer. Figure 4(c) shows the Lloyd quantizer for the Pdf in Figure 4(b). Note that the Lloyd algorithm assigns smaller cell sizes around the origin to approximate regions of a higher probability more accurately.

Vector Quantization

As shown in Table 2, the overhead of Huffman coding can be reduced by grouping samples together and encoding them as a single block. Moreover, as in dictionary coding, the grouping makes it easy for the encoder to exploit possible dependencies between samples. Vector quantization is the generalization of scalar quantization that quantizes a block of scalar samples jointly.

Figure 5 illustrates a two-dimensional vector quantizer that partitions a unit square $[0,1] \times [0,1]$ into seven cells. The black dot in a cell depicts the output point of the cell. In this quantizer, the configuration of these cells

Figure 5: An example of a 2D vector quantizer

is completely determined by the locations of the output points. More specifically, the i th cell C_i is given by

$$C_i = \{x \in [0,1] \times [0,1] : d(x, y_i) \leq d(x, y_j) \text{ for } 1 \leq j \leq 7\}$$

where y_i denotes the i th output point. A vector x belongs to the i th cell if y_i is the nearest output point to x among all output points. This configuration of cells is called the *Voronoi diagram of output points*, and the quantizer is called the *nearest neighbor quantizer*. With the nearest neighbor quantizer, the encoder needs to store only the codebook consisting of output points without requiring any information on the geometrical configuration of cells. For an input vector, the encoder compares its distances to the output points and records the index of the nearest output point.

If a set of output points is fixed, the Voronoi diagram is the best configuration of cells that minimizes the average distortion. Also, as in equation 4, the output points should be centroids of the corresponding cells to minimize the average distortion. Therefore, in the same way as the Lloyd algorithm, we can design a locally optimal vector quantizer for a Pdf by refining the configuration of cells and the locations of output points iteratively. This is called the *generalized Lloyd algorithm (GLA)* (Gersho and Gray 1991, Chapter 11).

Vector quantization has several advantages over scalar quantization. First, it can effectively exploit possible correlations between samples. Consider a two-dimensional random variable $X = (X_1, X_2)$ that is uniformly distributed over the two shaded quadrants in Figure 6(a). Because the marginal Pdf of X_1 or X_2 is uniform over the interval $[0,1]$, its optimal scalar quantizer is a uniform quantizer. If we encode each component independently by a four-point uniform scalar quantizer, the unit square is partitioned into sixteen rectangular cells as shown in Figure 6(b). This scheme requires 2 bits per component. However, note that components X_1 and X_2 are correlated with each other and the probability density over the upper-right and lower-left quadrants in Figure 6(a) is zero. Therefore, we can encode variable X with an eight-point vector quantizer in Figure 6(c), which requires only 1.5 bits per component while achieving the same distortion as given in Figure 6(b).

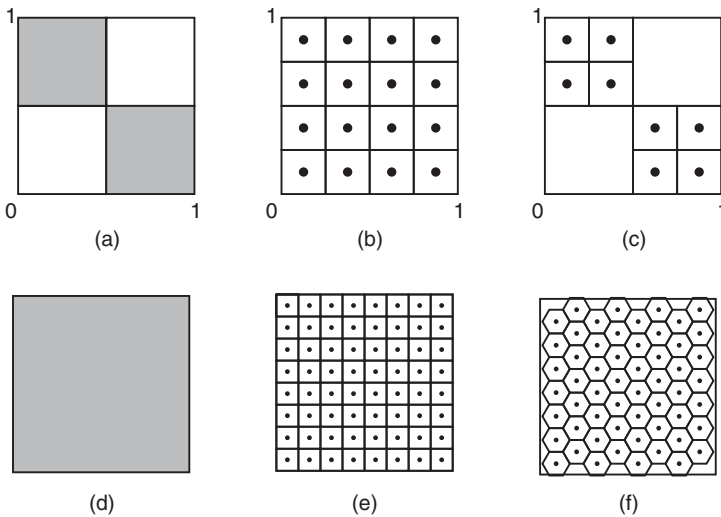

Figure 6: Advantages of vector quantization over scalar quantization (Gersho and Gray 1991, Chapter 11)-(a) probability density function; (b) scalar quantization for (a); (c) vector quantization for (a); (d) probability density function; (e) square cell partitioning for (d); (f) hexagonal cell partitioning for (d)

As shown in Figure 6(b), scalar quantization of each component leads only to a rectangular cell partitioning in the two-dimensional space. Similarly, it leads only to a cubic cell partitioning in the three-dimensional space and so on. In contrast, vector quantization has a freedom in choosing multidimensional cell shapes. Therefore, even if the components of a multidimensional variable are statistically independent, vector quantization can provide better performance than scalar quantization. For example, suppose that the components of a variable $X = (X_1, X_2)$ are independent of each other and uniformly distributed as shown in Figure 6(d). Figures 6(e) and 6(f) are a square partitioning and a hexagonal cell partitioning for this Pdf, respectively. The square cells and the hexagonal cells are of the same size. Thus, if we assume that the number of output points is large and the boundary effects are negligible, then the hexagonal partitioning requires the same rate as the square partitioning. However, the hexagonal partitioning provides lower average distortion than the square partitioning because the maximum distance between two points within the hexagon is smaller than that within the square.

Vector quantization is used to compress various kinds of data, including speech and image data. However, the main drawback of vector quantization is that it often requires a large storage space and high computational complexity. Consider a vector quantizer for image data that encodes each eight-by-eight pixel region as a block at the rate of 0.5 bits per pixel. Each block is encoded with $32 = 8 \times 8 \times 0.5$ bits and the codebook is, hence, composed of $2^{32} \approx 4 \times 10^9$ vectors. If each pixel value is represented with a single byte, then both the encoder and the decoder require about $8 \cdot 8 \cdot 4 \times 10^9$ bytes (≈ 256 Gbytes) to store the codebook. Also, if the nearest neighbor rule is used to find the code word, then a brute-force encoder would compute 4×10^9 vector distances to encode each block, which is not acceptable in practice. Hence, to reduce the storage space and the computational burden, several techniques have been developed such as *lattice vector quantization*, *tree-structured vector quantization*, and *shape-gain vector quantization* (Gersho and Gray 1991, Chapter 12).

Predictive Coding

Many data sources generate a sequence of samples that are highly correlated to one another. Hence, in many cases we can predict the future sample based on the past and current samples, although perfect prediction is not necessarily possible. Prediction plays an important role in data compression systems because it enables the removal of redundancy in data to achieve a high compression ratio. In predictive coding, the encoder predicts each sample from previous ones and transmits the prediction error instead of the original sample. Then the decoder makes the same prediction as the encoder and uses the prediction error to compute the original sample. The entropy of the prediction error is generally lower than that of the original sample; thus, the prediction error can be more compactly compressed with lossless or lossy compression tools.

Let us consider an image compression system. Figure 7(a) shows the Lena image and its enlarged face region. The image consists of 512×512 pixels. Each pixel

Figure 7: Lena images-(a) original image, (b) quantized image, and (c) image obtained by predictive quantization

Figure 8: Histograms of (a) original gray levels and (b) prediction errors

has a gray level within $[0, 255]$, and is represented by a single byte. Figure 8(a) is the histogram of gray levels obtained from other test images. For each gray level, the histogram shows the number of pixels in the test images that have that gray level. Thus, after normalization, the histogram can be employed as an approximation of the Pdf of gray levels. Based on the approximation of the Pdf, we can design a sixteen-point scalar quantizer using the Lloyd algorithm. The sixteen output points are

{16, 30, 42, 58, 70, 84, 98, 114, 129, 143, 159, 173, 187, 200, 209, 217}

Figure 7(b) is the image quantized by this quantizer. It can be observed that the quantization error degrades the image quality. The rate is 4 bits per pixel, and the mean squared error is 18.974. We use the mean squared error to evaluate image quality because it is easy to compute. However, other quantitative measures are designed to provide more accurate estimation of subjective image quality (Agaian, Panetta, and Grigoryan 2001).

We can achieve better performance using predictive coding techniques because adjacent pixels in typical images have similar gray levels. Suppose that the encoder compresses pixels in a raster scan order (Wang, Osterman, and Zhang 2002). Figure 8(b) is the histogram of prediction errors where each pixel is predicted from the average of the past three neighboring pixels: left, upper, and upper-right pixels. Note that the prediction errors are concentrated around 0 and much more compactly

Figure 9: (a) DPCM encoder; (b) DPCM decoder

distributed than the original pixel values in Figure 8(a). For this distribution, the codebook of the sixteen-point Lloyd quantizer is given by

$$\{-56, -35, -25, -19, -15, -11, -7, -3, 0, 4, 8, 12, 17, 21, 32, 53\}$$

Figure 7(c) is the image obtained by predictive quantization. During the prediction, the encoder uses the reconstructed values of past three pixels, instead of the original values, to avoid the mismatch between the encoder and the decoder. Then the encoder quantizes the prediction error and transmits the output index to the decoder. In the decoder, the same prediction is performed, and then the quantized error is added to the prediction value to reconstruct a pixel. Note that Figure 7(c) provides better image quality than Figure 7(b). The mean squared error is 5.956.

The general structure of a predictive quantization system (Gersho and Gray 1991, Chapter 7) is shown in Figure 9. This system is also called *differential pulse code modulation* (DPCM). The predictor, P, generates the prediction \hat{x}_n of the n th sample x_n based on the past reconstructed samples \tilde{x}_{n-i} ($i = 1, 2, \dots$). The most common predictor is the linear predictor, given by

$$\hat{x}_n = \sum_{i=1}^m a_i \tilde{x}_{n-i}, \quad (7)$$

where a_i 's are weighting coefficients. The quantizer Q quantizes the prediction error $en = x_n - \hat{x}_n$ into an output point \tilde{e}_n , and transmits the output index i_n . In the decoder, the dequantizer Q^{-1} converts the index i_n into the output point \tilde{e}_n , and adds it to the prediction \hat{x}_n to reconstruct \tilde{x}_n .

Transform Coding

In *transform coding*, a sequence of source samples is represented by another sequence of transform coefficients, whose energy is concentrated in relatively few coefficients. Because the coefficients have different statistics, they can be quantized more effectively than the original samples. In the decoder, the quantized coefficients are inverse transformed to reconstruct the samples.

The *discrete cosine transform* (DCT) (Jayant and Noll 1984, 558–60) provides excellent energy compaction for highly correlated data. The DCT of a sequence a is related to the *discrete Fourier transform* (DFT) and can be computed by fast algorithms based on the *fast Fourier transform* (FFT). Thus, it is employed in various image

and video compression standards. The DCT of an N -point sequence $a = (a_0, a_1, \dots, a_{N-1})$ is defined as

$$x_j = c_j \sum_{i=0}^{N-1} a_i \cos \left[\frac{\pi(2i+1)j}{2N} \right] \quad \text{for } j = 0, 1, \dots, N-1,$$

where $c_0 = \sqrt{1/N}$ and $c_j = \sqrt{2/N}$ for $j = 1, 2, \dots, N-1$.

The sequence of transform coefficients $x = (x_0, x_1, \dots, x_{N-1})$ can be inverse transformed into the original samples by

$$a_i = \sum_{j=0}^{N-1} c_j x_j \cos \left[\frac{\pi(2i+1)j}{2N} \right] \quad \text{for } i = 0, 1, \dots, N-1,$$

This can be rewritten as

$$a = \sum_{j=0}^{N-1} x_j b_j$$

where b_j is a basis vector, whose i th element is equal to $c_j \cos[(\pi(2i+1)j)/(2N)]$.

Figure 10 shows the eight basis vectors for the eight-point DCT. When j is low, the samples in b_j are slowly varying, and the coefficient x_j represents a low-frequency component in the signal. On the other hand, for high j , x_j represents a high-frequency component corresponding to rapid variations between samples. As mentioned previously, many data sources generate a sequence of highly correlated samples. In such a case, high-frequency coefficients usually have smaller magnitudes than low-frequency coefficients. For example, consider the sequence of samples

$$(97, 102, 117, 135, 139, 140, 137, 130).$$

The eight-point DCT of these samples yields the coefficients

$$(352.5, -37.5, -25.2, 2.1, 1.8, 4.1, -0.7, -1.1)$$

Note that most energy is concentrated in the first three coefficients. Let us assume that the encoder transmits only the first three coefficients after quantizing them into the nearest integers. Then the decoder fills in the other

Figure 10: Basis vectors for the 8-point DCT

coefficients with zeros and performs the inverse transform on

$$(353, -37, -25, 0, 0, 0, 0, 0)$$

to obtain approximate samples

$$(95.1, 104.6, 119.3, 132.7, 140.0, 139.9, 135.4, 131.4)$$

The reconstruction errors are relatively small, although only the first three quantized coefficients are employed in the reconstruction. In image compression systems, 2D-DCT is employed, and the transform coefficients are encoded by more sophisticated coding schemes such as *zonal* or *threshold coding* (Jain 1989, 508–10).

In most applications, the length of a signal is unbounded or too large to be transformed as a whole. Consequently, a source signal is partitioned into blocks of samples, and the DCT is applied independently to the blocks. In this case, the DCT is called a *block transform*. The DFT, the *discrete sine transform* (DST), the *Hadamard transform* are other examples of block transforms (Jain 1989, Chapter 5). The main disadvantage of block transforms is that they cannot exploit possible correlations between blocks.

Sub-Band and Wavelet Coding

Being different from block transforms, the *sub-band transform* involves no partitioning of samples, and thus possible correlations between blocks can be exploited. Figure 11 shows a two-channel sub-band coding system that transforms an input sequence into two frequency sub-bands. First, the encoder applies two analysis filters, H_0 and H_1 , to an input sequence a , respectively. Then the outputs are downsampled by a factor of 2 to generate two sequences, x_0 and x_1 . In general, H_0 is a low-pass filter and H_1 is a high-pass filter. Thus, x_0 represents low-frequency components in the original sequence, while x_1 represents high-frequency components. Both x_0 and x_1 can be quantized and coded differently according to their characteristics. In the decoder, the quantized sequences \tilde{x}_0 and \tilde{x}_1 are upsampled by inserting a zero between every two consecutive samples and then processed by synthesis filters G_0 and G_1 to reconstruct the input sequence approximately.

The analysis and synthesis filters can be designed so that the decoder reconstructs the original sequence losslessly when there is no quantization error (i.e., $\tilde{x}_0 = x_0$ and $\tilde{x}_1 = x_1$). If this condition is satisfied, then the set of the analysis and synthesis filters is called the *perfect reconstruction filter bank*. Several methods have been proposed for the design of perfect reconstruction filter banks,

driven by applications of sub-band coding of speech and image signals (Vetterli and Kovačević 1995, Chapter 3).

In the wavelet representation, a signal is hierarchically decomposed using a family of basis functions that is built by scaling and translating a single prototype function (Mallat 1989). The *wavelet transform* facilitates the multi-resolution analysis of a signal by reorganizing the signal as a set of details appearing at different resolutions. The wavelet transform has a close relationship with the sub-band transform, and the *discrete wavelet transform* (DWT) can be obtained by applying the two-channel sub-band transform to the low-pass sub-band recursively.

Figure 12 shows the sub-band decomposition of the Barbara image. First, we filter each row using two analysis filters and then downsample the filtered sequences to obtain low (L) and high (H) frequency sub-bands. In this Figure, the 9-7 filter bank (Antonini et al. 1992) is employed. Then, in the same way as the row decomposition, we decompose each column to obtain LL, LH, HL, and HH sub-bands.

This 2-D sub-band decomposition is recursively applied to the LL sub-band to obtain the DWT. Figure 13 shows the three-level wavelet decomposition of the Barbara image. The LL_3 sub-band approximates the original image at the coarsest resolution. The HL_i sub-bands contain vertical edge components at different resolutions ($i = 1, 2, 3$). Similarly, the LH_i and HH_i sub-bands contain horizontal and diagonal details, respectively. It can be seen that the signal energy is concentrated in the coefficients in the LL_3 sub-band. Therefore, the wavelet

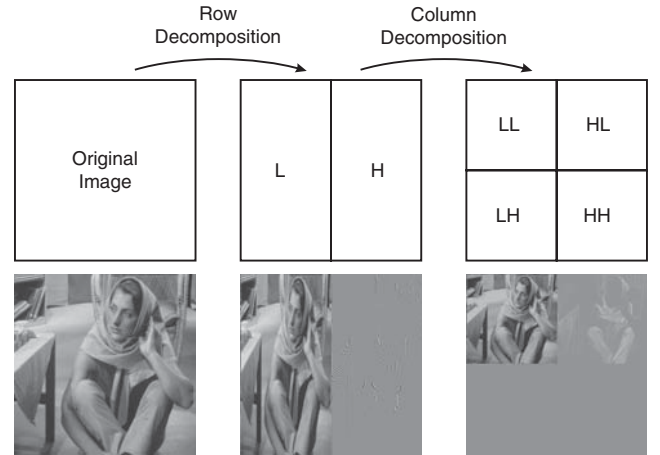

Figure 12: Sub-band decomposition

Figure 11: A sub-band coding system

Figure 13: Three-level wavelet decomposition

coefficients can be compressed effectively based on the adaptive quantization by allocating a higher bit rate to the LL_3 sub-band than to other sub-bands (Vetterli and Kovačević 1995, Chapter 7).

Shapiro (1993) proposed an image compression algorithm, called *embedded zerotree wavelet* (EZW). His algorithm exploits interband correlations of DWT coefficients using zerotrees. Figure 13 illustrates a zerotree. The twenty-one coefficients, depicted by dots, represent the horizontal edge components of the same region in the original image. Thus, if the one coefficient in the LH_3 sub-band is less than a threshold, it is probable that the other twenty coefficients in the finer sub-bands also are less than the threshold. In such a case, the twenty-one coefficients are said to form a zerotree. Shapiro combined the concept of zerotrees with bit-plane coding and adaptive arithmetic coding to compress the DWT coefficients efficiently. The DWT is also used in the recent image compression standard JPEG2000 (Taubman and Marcellin 2002).

APPLICATIONS

A data compression system can be conceptually divided into a data modeler and a parameter coder. To compress a certain type of data, its characteristics should be first analyzed and modeled. Then, according to the data model, parameters are extracted from input data and compressed using one or more techniques in the previous two sections. The compression performance depends on how accurately the source data are modeled as well as how efficient the parameter coder is.

For example, letters in a text can be modeled as independent variables and each letter can be Huffman encoded, irrespectively of its position in the text, according to the probability distribution of letters. Alternatively, we can adopt the model that the probability of a letter depends on the preceding letter and design several Huffman code word tables, one for each preceding letter. Similarly, the preceding n letters can be employed as a conditioning class, and a Huffman code word table can be designed for each conditioning class. As n increases, the characteristics of text data can be more accurately approximated,

and text data can be more compactly encoded at the cost of higher complexities of the encoder and the decoder (Bell, Cleary, and Witten 1990, Chapter 2).

Therefore, when designing the data modeler and the parameter coder, we need consider several requirements of an individual application, including the desired compression ratio, tolerable distortion, and complexities of the encoder and the decoder.

Several applications of text compression are considered below. The approaches and application areas of speech and audio compression, image compression, and video compression are described in *Image Compression*, *Video Compression*, and *Speech and Audio Compression*. By reducing the sizes of text files, we can use the limited storage space in a computer more effectively and save communication time for sharing files between computers. In the UNIX environment, “compress” and “gzip” are often used as file compression tools. Also, in PC environments, ARJ and ZIP are popular compression tools. All of these tools are variations of Lempel-Ziv dictionary coding techniques. They can losslessly compress typical text data to 30 percent to 40 percent of its original size because text data contain many redundancies and frequently recurring patterns.

Recently, context-based adaptive arithmetic coding has been studied to compress text data more efficiently (Witten, Neal, and Cleary 1987). Moffat, Neal, and Witten (1998) reported that their arithmetic coder requires 2.20 bits/letter for a text file excerpted from the *Wall Street Journal*, while the “gzip” utility requires approximately 2.91 bits/letter. The text file has the zero-order letter entropy of 4.88 bits/letter, which is the minimum required bit rate when letters are modeled as independent variables.

CONCLUSION

Data compression is one of the key technologies that enable Internet and mobile communications. It has been extensively studied since the late 1960s, and various compression algorithms have been developed to store and transmit multimedia data efficiently. In this chapter, we classified data compression into lossless and lossy techniques and described key algorithms for each class.

GLOSSARY

Code: A set of binary strings assigned to symbols of a data source.

Code word: A binary string in a code.

Compression ratio: The ratio of original data size to compressed data size.

Data coding: A synonym for data compression.

Data compression: A mechanism of representing data in a compact way.

Decoder: A device that reproduces original data from compressed data.

Decompression: A mechanism of reproducing original data from compressed data.

Encoder: A device that compresses data.

Entropy: The amount of information or uncertainty in a data source, or the minimum number of bits required on average to describe a sample of the data source.

Lossless compression: Compressing data such that an exact duplicate of the original data can be reproduced at the decoder.

Lossy compression: Data compression that allows loss of information.

INTRODUCTION

Image compression can generally be categorized into lossless and lossy compression. Obviously, lossless compression is most desirable because the reconstructed image is an exact copy of the original. The compression ratios that can be obtained with lossless compression, however, are fairly low and typically range from three to five, depending on the image. Such low compression ratios are justified in applications where no loss of quality can be tolerated, which is often the case in the compression and storage of medical images. For most other applications such as Internet browsing and storage for printing, some loss is usually acceptable. Allowing for loss then allows for much higher compression ratios.

Early image compression algorithms have mainly focused on achieving low distortion for a given, fixed bit rate, or, conversely, on achieving the lowest rate for a given maximum distortion. Although these goals are still valid, modern multimedia applications have led to a series of further requirements such as spatial and *signal-to-noise ratio* (SNR) scalability and random access to parts of the image data. For example, in a typical Internet application, the same image is to be accessed from various users with a wide range of devices (from a low-resolution palm top computer to a multimedia workstation) and via channels ranging from slow cable modems or wireless connections to high-speed wired local area networks. To optimally utilize available bandwidth and device capabilities, it is desirable to transcode image data within the network to the various resolutions that best serve the respective users. On-the-fly transcoding, however, requires that compressed image data be organized in such a way that different content variations can be easily extracted from a given high-resolution code stream. The new JPEG 2000 standard takes a step in this direction and combines abundant functionalities with a high compression ratio and random code stream access.

It is also worth mentioning that image coders are usually asymmetrical in the sense that the encoding process takes much more computational power than the decoding.

This is because the encoder often needs to select the best compression strategy and parameters for a given image or image region before it can start encoding the intensity values, whereas the decoder just receives the encoder's selection and code stream and decodes it in a straightforward manner. The compression standards often only specify the decoder, leaving room for developers to optimize their encoders.

This chapter gives an overview of some of the most important image compression tools and techniques. We first look at an introductory example that already shows some of the key ideas behind image compression. Then we discuss the theoretical background of data compression and review the discrete cosine and wavelet transforms, which are the two most important transforms in image compression. Subsequently, we look at state-of-the-art embedded wavelet compression methods and give an overview of standards for the compression of images. Finally, a number of conclusions and an outlook are given.

AN INTRODUCTORY EXAMPLE OF IMAGE COMPRESSION

Consider the gray-scale image in Figure 1a. There are 256 possible levels of gray that are commonly expressed by integer numbers ranging from zero (black) to 255 (white). The encoding requires 8 *bits per pixel* (bpp) when a fixed-length code is used. To achieve a compression ratio of 8, we can quantize the pixels to 1 bit, expressing whether a pixel value is larger than 127. The resulting decoded image can be seen in Figure 1b, where only two different levels of gray are visible.

Figure 1c shows the magnitude of the *two-dimensional discrete Fourier transform* (2D-DFT) of the image. We see that most of the signal energy is concentrated in the low-frequency range (the center of Figure 1c), which results from the fact that the image has flat regions with approximately the same level of gray. In a subsequent step, the frequency-domain representation has been quantized with equal step size for all coefficients and then encoded

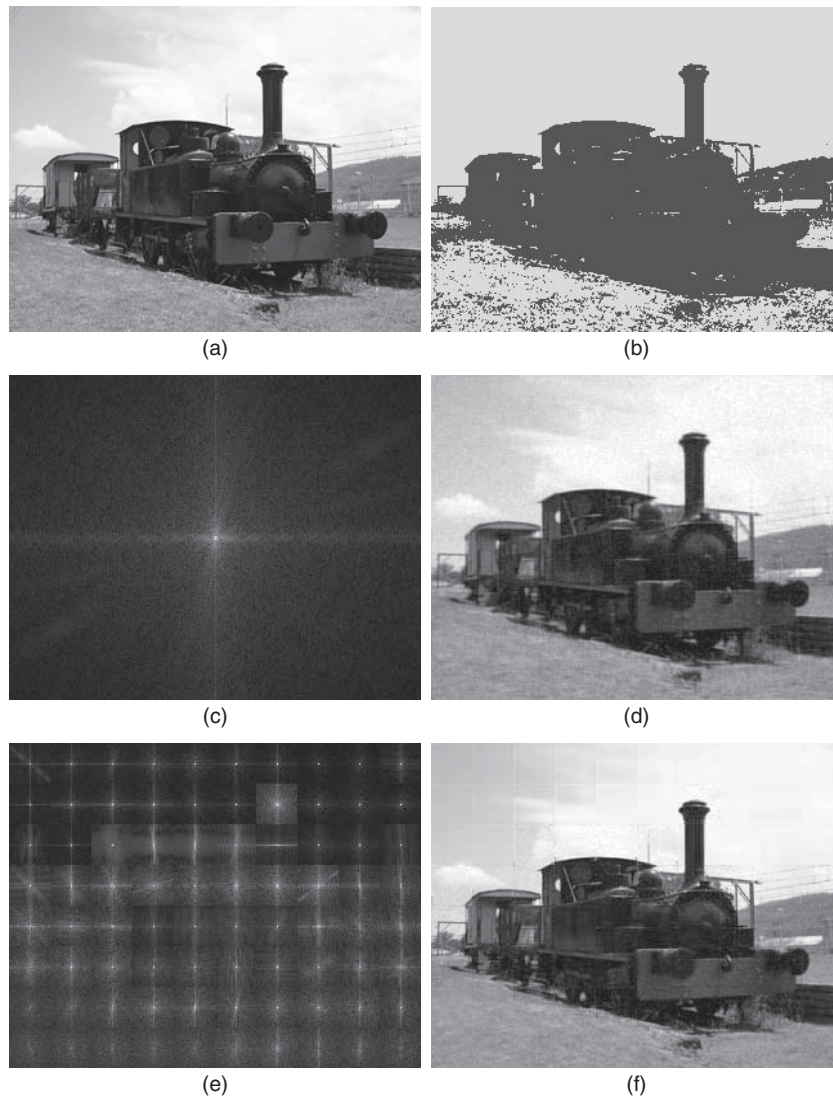

Figure 1: Example of image compression. (a) The original image with a size of 256×320 pixels and 256 levels of gray. (b) Image directly quantized and encoded at 1 bpp. (c) Fourier transform of the image, with frequency axes ranging from $-\pi$ to π in both horizontal and vertical directions. (d) Image reconstructed from quantized Fourier coefficients at a rate of 1 bpp. (e) Fourier transform carried out on blocks of 32×32 pixels. (f) Image reconstructed from quantized block-wise Fourier coefficients at a rate of 1 bpp.

with a Huffman code (see below). In this case, most of the bits are spent for transmitting the large low-frequency coefficients, and only few bits are used for the high-frequency content. The result of encoding the image at a rate of 1 bpp is depicted in Figure 1d. We see that the quality is already much better than for the direct image quantization.

Actual coding standards do not transform the entire image but usually divide it into smaller blocks in order to have a better chance of capturing flat regions in the blocks and limit the spreading of individual quantization errors over the entire reconstructed image. The magnitude of a blockwise 2D-DFT with block size 32×32 is depicted in Figure 1e. The reconstructed image after quantization and Huffman encoding at 1 bpp is shown in Figure 1f. Now the quality within each block is better than in Figure 1d, but the block boundaries become clearly visible. Further reducing the block size reduces the visibility

of block boundaries, but overdoing this reduces the coding efficiency, with 1-pixel blocks being the limit. Most block-based coding standards adopt a block size of 8×8 pixels. Instead of the DFT, one often uses the discrete cosine transform (see below). A way to achieve high coding efficiency without blocking artifacts is to use overlapping blocks, which is the case for the wavelet transform discussed later in this chapter.

ELEMENTS OF SOURCE CODING THEORY

The Rate-Distortion Trade-Off

The mathematical background that describes the trade-off between compression ratio and fidelity was established by Shannon (1959) in his work on rate-distortion (RD) theory. To study the implications of the theoretical

Figure 2: Distortion-rate curves for different coders

results obtained by Shannon on the performance of any practical coder, we consider the graphs in Figure 2 that show the distortion obtained with different coders versus the rate required to store the information. Such graphs obtained for a specific image and encoding algorithm are known as *operational distortion-rate curves*. The distortion is typically measured as the *mean squared error* (MSE) between the original and the reconstructed image, and the rate is measured as the required average number of bits per pixel.

As one might expect, all coders show the same maximum distortion at rate zero (no transmission). With increasing rate, the distortion decreases and different coders reach the point of zero distortion at different rates. Coder 1 is an example of a coder that combines lossy and lossless compression in one bit stream and that is optimized for lossless compression. Coder 2, on the other hand, is a lossy coder that shows good performance for low rates but reaches the lossless stage only at extremely high rates. The lowest curve shows the minimum rate required to code the information at a given distortion, assuming optimal compression for any rate. This is the desired curve, combining lossy and lossless compression in an optimal way.

Coding Gain through Decorrelation

The simplest way to compress an image in a lossy manner would be to quantize all pixels separately and provide a bit

stream that represents the quantized values. This strategy is known as *pulse code modulation* (PCM). For example, an 8-bit gray-scale image whose pixels $x_{m,n}$ are integers in the range from 0 to 255 could be compressed by a factor of four through neglecting the six least-significant bits of the binary representations of $x_{m,n}$, resulting in an image with only four different levels of gray. Entropy coding (see below) of the PCM values would generally allow for increased compression, but such a strategy would still yield a poor trade-off between the amount of distortion introduced and the compression ratio achieved. The reason for this poor behavior of PCM is that the spatial relationships between pixels are not utilized.

Images usually contain a large amount of spatial correlation that can be exploited to obtain compression schemes with a better RD trade-off than that obtained with PCM. For this, the data first need to be decorrelated, and then quantization and entropy coding can take place. Figure 3 shows the basic structure of an image coder that follows such a strategy. The quantization step is to be seen as the assignment of a discrete symbol to a range of input values. In the simplest case, this could be the assignment of symbol a through the operation $a = \text{round}(x/q)$ where q is the quantization step size. The inverse quantization then corresponds to the recovery of the actual numerical values that belong to the symbols (e.g., the operation $\hat{x} = q \cdot a$). The entropy coding stage subsequently endeavors to represent the generated discrete symbols with the minimum possible number of bits. This step is lossless. Errors occur only because of quantization.

One of the simplest decorrelating transforms is a prediction error filter that uses the knowledge of neighboring pixels to predict the value of the pixel to be encoded and then outputs the prediction error made. In this case, the coding paradigm changes from PCM to *differential PCM* (DPCM). To give an example, Figure 4 shows a neighborhood relationship where the previously decoded pixel values $x_{m-1, n-1}$, $x_{m-1, n}$, $x_{m-1, n+1}$ and $x_{m, n-1}$ can be used to predict the actual value $x_{m, n}$. A coding gain of DPCM over PCM arises from the fact that the prediction error usually has much less power than the signal itself and can therefore be compressed more efficiently.

Modern state-of-the-art image compression algorithms use transforms such as the *discrete cosine transform* (DCT) or the *discrete wavelet transform* (DWT) to

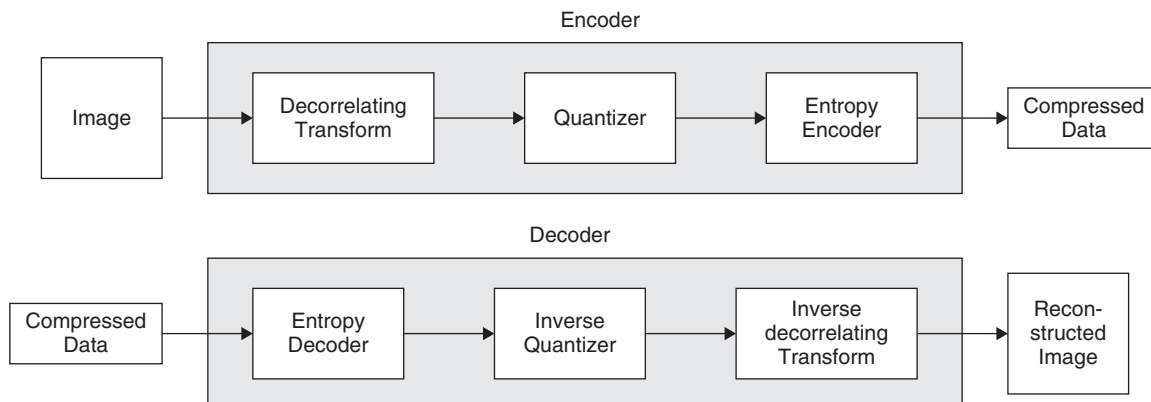

Figure 3: Typical image encoder and decoder structures

Figure 4: Context modeling

Figure 5: Transform coding

carry out decorrelation. These transforms are extremely efficient in decorrelating the pixels of an image and are employed in several compression standards such as JPEG (Wallace 1992) and JPEG 2000 (Joint Photographic Experts Group 2000).

To see how and why *transform coding* works, we consider the system in Figure 5. The input is a zero-mean random vector $x = [x_0, x_1, \dots, x_{M-1}]^T$ with correlation matrix $R_{xx} = E[xx^T]$, where $E[\cdot]$ denotes the expectation operation. The output $y = Tx$ of the transform is then a zero-mean random process with correlation matrix $R_{yy} = TR_{xx}T^T$. Because the random variables y_0, y_1, \dots, y_{M-1} stored in y may have different variances, they are subsequently quantized with different quantizers Q_0, Q_1, \dots, Q_{M-1} . In the synthesis stage, the inverse transform is applied to reconstruct an approximation \hat{x} of the original vector x based on the quantized coefficients $\hat{y}_0, \hat{y}_1, \dots, \hat{y}_{M-1}$. The aim is to design the system in such a way that the MSE $E[\|x - \hat{x}\|^2] = \sum_{k=0}^{M-1} E[(x_k - \hat{x}_k)^2]$ becomes minimal for a given total bit budget. Three questions arise: (1) What is the optimal transform T given the properties of the source? (2) How should an available bit budget B be distributed to the different quantizers? (3) What are the optimal quantization levels? Answers to these questions have been derived for both unitary and biorthogonal transforms. We will briefly discuss the results for the unitary case.

The optimal scalar quantizers Q_k that minimize the individual error variances $\sigma_{d_k}^2 = E_{q_k}[y_k - \hat{y}_k]^2$ for a given number of quantization steps are known as Lloyd-Max quantizers (Lloyd 1957; Max 1960). Important properties of these optimal quantizers are $E[q_k] = 0$ (zero-mean error) and $E[q_k \hat{y}_k] = 0$ (orthogonality between the quantized value and the error). When assuming such optimal quantizers in a transform-coding framework and restricting the overall average bit rate to a budget B , one obtains the bit-allocation rule $2^{B_k} \sim \sigma_{y_k}^2$, where B_k is the number of

bits spent to encode y_k and $\sigma_{y_k}^2$ is the variance of y_k (Jayant and Noll 1984). This rule intuitively makes sense as more bits are assigned to random variables with a larger variance. Moreover, another important result is that in an optimal setting, each quantizer contributes equally to the total output distortion.

To answer the question which transform is optimal for a given coding task, we consider the coding gain defined as $G_{TC} = \sigma_{PCM}^2 / \sigma_{TC}^2$ where σ_{PCM}^2 is the error variance of simple PCM and σ_{TC}^2 is the error variance produced by transform coding, both at the same average bit rate B . With the optimal quantizers discussed above, one obtains (Jayant and Noll 1984)

$$G_{TC} = \frac{1}{M} \sum_{k=0}^{M-1} \sigma_{y_k}^2 \left(\prod_{k=0}^{M-1} \sigma_{y_k}^2 \right)^{1/M}$$

which is the ratio of the arithmetic and geometric mean of the coefficient variances. Among all unitary transforms T , this quotient is maximized when R_{yy} is diagonal and thus when the transform coefficients are uncorrelated. This decorrelation is accomplished by the *Karhunen-Loève transform* (KLT).

The expression for the coding gain can be interpreted as follows:

1. A maximum coding gain is obtained if the coefficients y_k are mutually uncorrelated.
2. The more unequal the variances $\sigma_{y_k}^2$ are, the higher the coding gain is because a high dissimilarity leads to a high ratio of arithmetic and geometric mean. Consequently, if the input values x_k are already mutually uncorrelated a transform cannot provide any further coding gain.
3. With increasing M , one may expect an increasing coding gain that moves toward an upper limit as M goes to infinity. In fact, one can show that this is the same limit as the one obtained for DPCM with ideal prediction (Jayant and Noll 1984).

It is interesting to note that the above-mentioned expression for the coding gain also holds for *sub-band coding* based on uniform, energy-preserving filter banks. A more general expression for the coding gain has been derived by Katto and Yasuda (1991). Their formula also holds for biorthogonal transform and sub-band coding as well as other schemes such as DPCM.

Vector Quantization

Vector quantization (VQ) is a multidimensional extension of *scalar quantization* in that an entire vector of values is encoded as a unit. Let x be such an N -dimensional vector of values, and let $x_i, i = 1, 2, \dots, I$ be a set of N -dimensional code vectors stored in a codebook. Given x , a vector quantizer finds the code vector x_i from the codebook that best matches x and transmits the corresponding index i . Knowing i , the receiver reconstructs x as x_i . In the simplest case, one could think of x as being a block of an image, and then the code vectors x_i would be images as well.

An often-used quality criterion to determine which vector from the codebook gives the best match for x is the Euclidean distance $d(x, x_i) = \|x - x_i\|^2$. Theoretically, if the vector length N tends to infinity, then VQ becomes optimal and approaches the performance indicated by rate-distortion theory. In practice, however, the cost associated with searching a large codebook is the major obstacle. See Gersho and Gray (1991) for discussions of computationally efficient forms of the VQ technique and details on codebook design.

Fractal Coding

The idea of fractal coding is to exploit the self-similarity of the content of an image in different resolutions and at different locations. Given an image x , the encoder determines a contractive affine transformation T with a fixed point being close to x and transmits the parameters of T . The decoder iterates the transform T , starting from an arbitrary image and converging to the fixed point of T . The method yields good results on certain classes of images, but it is not widely used and lacks the efficiency and flexibility of transform- and wavelet-based coders.

Block-Truncation Coding

Block-truncation coding (BTC) (Delp and Mitchell 1979) is a lossy, block-adaptive encoding scheme that operates on small image regions. It quantizes a local region of an image in such a way that a number of moments are preserved in the quantized output. If, for example, the mean and variance are to be preserved, the encoder transmits two reconstruction values a and b together with a bitmap indicating whether a pixel is above or below a threshold. If a pixel value is below the threshold, it is reconstructed as a , otherwise as b . The values a and b are chosen to preserve the mean and variance within the block. Extensions to higher-order moments are possible.

Entropy Coding

Assigning the same code length to all symbols generated by a source is not optimal when the different symbols occur with different probabilities. In such a case, it is better to assign short code words to symbols that occur often and longer code words to symbols that occur only occasionally. The latter strategy results in variable-length codes and is the basic principle of entropy coding. Variable-length codes are employed in lossless image compression as well as for the compression of quantizer indices in lossy schemes.

A simple source model is the *discrete memoryless source* (DMS), which produces random variables X_i taken from an alphabet $A = \{a_1, a_2, \dots, a_L\}$. The symbols a_i may, for example, identify the various steps of a quantizer and are assumed to occur with probabilities $p(a_i)$. The first-order entropy of the source is defined as

$$H = -\sum_{i=1}^L p(a_i) \log_2 p(a_i)$$

and describes the average information per symbol (in bits). According to this expression, the more skewed the

probability distribution, the lower the entropy. For any given number of symbols L the maximum entropy is obtained if all symbols are equally likely. The entropy provides a lower bound for the average number of bits per symbol required to encode the symbols emitted by a DMS.

The best-known entropy-coding methods are *Huffman coding*, *arithmetic coding*, and *Lempel-Ziv coding*. Huffman coding produces a uniquely decipherable prefix code. As an example, consider the symbols a_1, a_2, a_3, a_4 that occur with probabilities 0.5, 0.25, 0.125, 0.125, respectively. A fixed-length code would use 2 bits per symbol. A possible Huffman code is given by $a_1 : 0, a_2 : 10, a_3 : 110, a_4 : 111$. This code only requires 1.75 bits per symbol on average, which is the same as the entropy of the source. In fact, one can show that Huffman codes are optimal and reach the lower bound stated by the entropy when the symbol probabilities are powers of 1/2. To decode a Huffman code, the decoder must know the code table that has been used by the encoder. In practice, this means that either a specified standard code table must be employed or the code table must be transmitted to the decoder as side information.

In arithmetic coding, there is no one-to-one correspondence between symbols and code words; the coding assigns variable-length code words to variable-length blocks of symbols. The code word representing a sequence of symbols is a binary number that points to a subinterval of the interval $[0,1)$ that is associated with the given sequence. The length of the subinterval is equal to the probability of the sequence, and each possible sequence creates a different subinterval. The advantage of arithmetic over Huffman coding is that it usually results in a shorter average code length, and arithmetic coders can be made adaptive to learn the symbol probabilities on the fly so that no side information in form of a code table is required.

In 1977 and 1978, Lempel and Ziv published two universal coding methods that are commonly referred to as LZ77 and LZ78, respectively. Universal coding aims at asymptotically achieving the lowest possible bit rate without having prior knowledge of the distribution of symbols. It does this by encoding entire phrases of symbols at once. In 1984, Welch published the LZW algorithm (Welch 1984), which is a modified version of LZ78. The LZW algorithm became quite popular in image compression because of its use in the GIF format (see below), but it incurred licensing royalties, so several software developers looked for alternatives such as modifications to the older LZ77 algorithm.

TRANSFORMS FOR IMAGE COMPRESSION

The Discrete Cosine Transform

The *discrete cosine transform* (DCT) is used in most current standards for image and video compression. Examples are JPEG, MPEG-1, MPEG-2, MPEG-4, H.261, H.263, and H.264. To be precise, there are four different DCTs defined in the literature; according to the categorization introduced by Rao and Yip (1990), it is the DCT-II that is

used for image compression. Because there is no ambiguity throughout this text, we will simply call it the DCT.

The DCT of a two-dimensional signal $x_{m,n}$ with $m, n = 0, 1, \dots, M-1$ is defined as

$$y_{k,\ell} = \frac{2\gamma_k\gamma_\ell}{M} \sum_{m=0}^{M-1} \sum_{n=0}^{M-1} x_{m,n} \cos \frac{k(m+\frac{1}{2})\pi}{M} \times \cos \frac{\ell(n+\frac{1}{2})\pi}{M}, \quad k, \ell = 0, 1, \dots, M-1$$

with

$$\gamma_k = \begin{cases} 1/\sqrt{2} & \text{for } k = 0 \\ 1 & \text{otherwise.} \end{cases}$$

The DCT is a unitary transform, so the inverse transform (2D-IDCT) uses the same basis sequences. It is given by

$$x_{m,n} = \sum_{k=0}^{M-1} \sum_{\ell=0}^{M-1} \frac{2\gamma_k\gamma_\ell}{M} y_{k,\ell} \cos \frac{k(m+\frac{1}{2})\pi}{M} \times \cos \frac{\ell(n+\frac{1}{2})\pi}{M}, \quad m, n = 0, 1, \dots, M-1$$

The popularity of the DCT comes from the fact that it almost reaches the coding gain obtained by the KLT for typical image data while having implementation advantages. Fast implementations can be obtained through the use of FFT algorithms or through direct factorization of the DCT formula (Rao and Yip 1990). The latter approach is especially interesting for the two-dimensional case where two-dimensional factorizations led to the most efficient implementations (Duhamel and Guillemot 1990; Fang, Hu, and Shih 1999).

In image compression, the DCT is usually used on non-overlapping 8×8 blocks of the image rather than on the entire image in one step. The following aspects have led to this choice. First, from the theory outlined above and the good decorrelation properties of the DCT for smooth signals, it is clear that, to maximize the coding gain for typical images, the blocks should be as big as possible. On the other hand, with increasing block size, the likelihood of capturing a nonstationary behavior within a block increases. This, however, decreases the usefulness of the DCT for decorrelation. Finally, quantization errors made for DCT coefficients will spread out over the entire block after reconstruction via the IDCT. At low rates, this can lead to annoying artifacts when blocks comprise a combination of flat and highly textured regions or if there are significant edges within a block. These effects are less visible if the block size is small. Altogether, the choice of 8×8 blocks has been found to be a good compromise between exploiting neighborhood relations in smooth regions and avoiding annoying artifacts because of inhomogeneous block content.

Figure 6 shows an example of the blockwise 2D-DCT of an image. The original image of Figure 6a has a size of 144×176 pixels, and the block size for the DCT is 8×8 . Figure 6b shows the blockwise-transformed image, and Figure 6c shows the transformed image after re-arranging the coefficients in such a way that all coefficients

(a)

(b)

(c)

Figure 6: Example of a blockwise 2-D DCT of an image. (a) Original image (144×176 pixels); (b) transformed image (block size 8×8 , 18×26 blocks); (c) transformed image after reordering of coefficients (8×8 subimages of size 18×26)

with the same physical meaning (i.e., coefficients $y_{k,\ell}$ from the different blocks) are gathered in a subimage. For example, the subimage in the upper-left corner of Figure 6c contains the coefficients $y_{0,0}$ of all the blocks in Figure 6b. These coefficients are often called *DC coefficients* because they represent a constant signal equal to the average pixel value within a block. Correspondingly, the remaining sixty-three coefficients of a block are called *AC coefficients*. From Figure 6c, one can see that the DC coefficients carry the most important information on the entire image. Toward the lower-right corner of Figure 6c, the amount of signal energy decreases significantly.

The Discrete Wavelet Transform

The discrete wavelet transform (DWT) is a tool to hierarchically decompose a signal into a multiresolution pyramid. It offers a series of advantages over the DCT. For example, contrary to the blockwise DCT, the DWT has overlapping basis functions, resulting in less-visible artifacts when coding at low bit rates. Moreover, the

Figure 7: Two-channel filter bank

multiresolution signal representation offers functionalities such as spatial scalability in a simple and generic way. Although most of the image compression standards are based on the DCT, the new still image compression standard JPEG 2000 and parts of the MPEG-4 multimedia standard rely on the DWT (Joint Photographic Experts Group 2000; Moving Picture Experts Group 1999). Also, the FBI standard for the compression of fingerprints uses the wavelet transform (Brislaw 1995).

For discrete-time signals, the DWT is essentially an octave-band signal decomposition that is carried out through successive filtering operations and sampling-rate changes. The basic building block of such an octave-band filter bank is the two-channel structure depicted in Figure 7. The terms $H_k(z)$ and $G_k(z)$ in Figure 7 denote the z -transforms of the respective filter impulse responses $h_k(n)$ and $g_k(n)$, $k = 0, 1$, where the z -transform of a sequence $a(n)$ is computed as $A(z) = \sum_{n=-\infty}^{\infty} a(n)z^{-n}$. $H_0(z)$ and $G_0(z)$ are low-pass filters, whereas $H_1(z)$ and $G_1(z)$ are high-pass filters. The blocks with arrows pointing downward indicate downsampling by factor two (i.e., taking only every second sample), and the blocks with arrows pointing upward indicate upsampling by two (insertion of zeros between the samples). Downsampling serves to eliminate redundancies in the sub-band signals, while upsampling is used to recover the original sampling rate. Because of the filter characteristics (low pass and high pass), most of the energy of a signal $x(n)$ with low-pass characteristic will be stored in the sub-band samples $y_0(m)$. Because $y_0(m)$ occurs at half the sampling rate of $x(n)$, it appears that the filter bank structure concentrates the information in fewer samples as it is required for efficient compression. More efficiency can be obtained by cascading two-channel filter banks to obtain octave-band decompositions or other frequency resolutions. For the structure in Figure 7 to allow perfect reconstruction (PR) of the input with a delay of n_0 samples [i.e., $\hat{x}(n) = x(n - n_0)$], the filters must satisfy

$$H_0(-z)G_0(z) + H_1(-z)G_1(z) = 0$$

and

$$H_0(z)G_0(z) + H_1(z)G_1(z) = 2z^{-n_0}$$

The first equation guarantees that the aliasing components that are present because of the subsampling operation will be compensated at the output; the second equation ensures that no amplitude distortions occur. In addition to the above-mentioned PR conditions, the filters should satisfy $H_0(1) = G_0(1) = \sqrt{2}$ and $H_1(1) = G_1(1) = 0$, which are essential requirements to make them valid wavelet filters. Moreover, they should satisfy some regularity constraints as described in (Daubechies 1992). It should be noted that the above two PR constraints hold for biorthogonal

two-channel filter banks. Paraunitary (energy-preserving) filter banks and the corresponding orthonormal wavelets additionally require the stronger condition

$$\left| H_0(e^{j\omega}) \right|^2 + \left| H_0(e^{j(\omega+\pi)}) \right|^2 = 2$$

to hold. Apart from the special case where the filter length is two, this condition can only be satisfied by filters with nonsymmetric impulse responses (Vaidyanathan 1985). Because symmetric filters are highly desirable because they allow for simple boundary processing (see below), paraunitary two-channel filter banks and the corresponding orthonormal wavelets are seldom used in image compression.

For the decomposition of images, the filtering and downsampling operations are usually carried out separately in the horizontal and vertical directions. Figure 8 illustrates the principle. To ensure that the analysis process results in the same number of sub-band samples as there are input pixels, special boundary processing steps are required. These will be explained below. An example of the decomposition of an image is depicted in Figure 9. One can see that the DWT concentrates the essential information on the image in a few samples, resulting in a high coding gain.

When decomposing a finite-length signal (a row or column of an image) with a filter bank using linear convolution, the total number of sub-band samples is generally higher than the number of input samples. Methods to resolve this problem are *circular convolution* (Woods and O'Neil 1986), *symmetric extension* (Smith and Eddins 1990; Bradley, Brislawn, and Faber 1992) and *boundary filtering* (de Queiroz 1992; Herley 1995; Mertins 2001). In the following, we will describe the method of symmetric extension, which is the one most often used in practice. It requires the filters in the filter bank to have linear phase, which means that biorthogonal filters or wavelets must be used. We will address the procedure for filters with odd and even length separately.

If the filter impulse responses have odd lengths, then linear phase means that they obey the *whole sample symmetry* (wss) shown in Figure 10a or they have whole sample asymmetry. For filters with wss, which are common in image compression, the symmetric extension of the signal has to be carried out with wss as well, as depicted in Figure 10b. A signal of length N is thus extended to a periodic signal $x_{\text{wss}}(n)$ with period $2N - 2$ and symmetry within each period. When decomposing such an extended signal with the corresponding analysis filter bank, the obtained sub-band signals will also be periodic and show symmetry within each period. The type of sub-band symmetry depends on the filter and signal lengths. For the case where

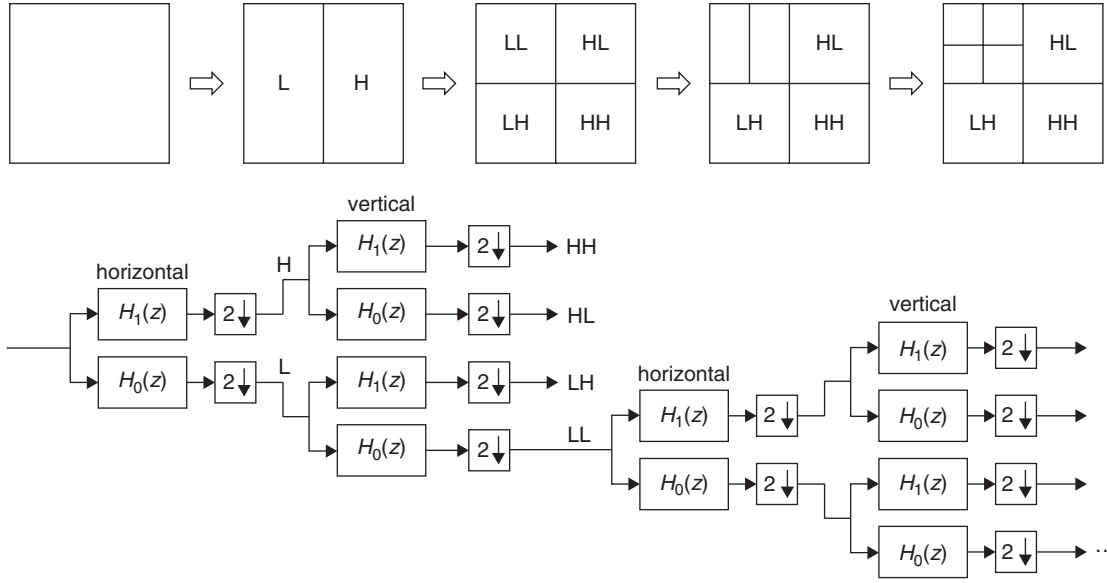

Figure 8: Separable two-dimensional octave-band filter bank

Figure 9: Example of a two-dimensional octave-band decomposition

N is even, the obtained sub-band symmetries are depicted in Figures 10c and 10d. One can easily see that only a total number of N distinct sub-band samples need to be stored or transmitted, because from these N samples the periodic sub-band signals can be completely recovered. Feeding the periodic sub-band signals into the synthesis filter bank and taking one period of the output finally yields perfect reconstruction.

Linear-phase filters with even length have the *half-sample symmetry* (hss) in Figure 11a for the low-pass and the *half-sample antisymmetry* (hsas) in Figure 11b for the high-pass. In this case, the hss extension in Figure 11c is required, resulting in an extended signal with period $2N$ and symmetry within each period. Again, the sub-band signals show symmetries that can be exploited to capture the entire information on a length- N input signal in a total number of N sub-band samples. The sub-band symmetries obtained for even N are depicted in Figures 11d and 11e.

Note that the extension schemes described above can also be used for cases where N is odd, resulting in different sub-band symmetries. Moreover, with the introduction of two different subsampling phases, they can be used to define nonexpansive DWTs for arbitrarily shaped objects (see, e.g., Danyali and Mertins 2004 and the references therein).

EMBEDDED WAVELET CODING

Early wavelet image coders used to employ run-length and entropy coding for further compression of the quantized wavelet coefficients. Run-length coding was found particularly useful for coding long stretches of zeros that frequently occur within the higher bands. Although such coders can perform reasonably well for a fixed bit rate, they do not offer much flexibility, and especially do not allow for progressive transmission of the wavelet coefficients in terms of accuracy. A new era of wavelet coders

Figure 10: Symmetric extension for odd-length filters. (a) Impulse response with whole sample symmetry (wss); (b) periodic extension with wss of a signal with length $N = 4$ (the original signal is marked with black dots); (c) sub-band periodicity obtained for filter lengths $L = 3 + 4k$ with k being an integer; (d) sub-band periodicity for filter lengths $L = 5 + 4k$

Figure 11: Symmetric extension for even-length filters. (a) Impulse response with half-sample symmetry (hss); (b) half-sample antisymmetry (hsas); (c) periodic signal extension with half-sample symmetry; (d) hss-hss, obtained with hss filter; (e) hsas-hsas, obtained with hsas filter

started with Shapiro's *embedded zerotree wavelet* (EZW) coder (Shapiro 1993), which was the first coder that looked at simultaneous relationships between wavelet coefficients at different scales and produced an entirely embedded code stream that could be truncated at any point to achieve the best reconstruction for the number of symbols transmitted or received. The key idea of the EZW coder was the introduction of *zerotrees*, which are sets of coefficients gathered across scales that are all quantized to zero with regard to a given quantization step size and can be coded with a single symbol. All coefficients within a zerotree belong to the same image region. The formation of zerotrees and the parent-child relationships within a zerotree are shown in Figure 12a. From looking at the wavelet transform in Figure 9, it is clear that it is quite likely that all coefficients in such a tree may be quantized to zero in a smooth image region. The concept of EZW coding was refined by Said and Pearlman (1996), who proposed a coding method known as *set partitioning in hierarchical trees* (SPIHT), a state-of-the-art coding method that offers high compression and fine granular SNR scalability. Both the EZW and SPIHT coders follow the idea of transmitting the wavelet coefficients in a semi-ordered manner, bit plane by bit plane, together with the sorting information required to identify the positions of the transmitted coefficients.

In the following, we will have a closer look at the SPIHT coder, which is more efficient in transmitting the sorting information. In fact, the SPIHT algorithm is so efficient that additional arithmetic coding will only result in marginal improvements (Said and Pearlman 1996).

The SPIHT coder uses three lists to organize the sorting of coefficients and the creation of the bit stream. These are a *list of insignificant pixels* (LIP), a *list of insignificant sets* (LIS), and a *list of significant pixels* (LSP). During initialization, the coordinates of the coefficients in the lowest band are stored in the LIP, and three-quarters of them are also stored in the LIS where they are seen as roots of insignificant sets. Figure 12b illustrates the structure of a set where each coefficient has four offspring. The LSP is left empty at this stage. A start threshold T is defined as $T = 2^n$ with $n = \lceil \log_2(y_{\max}) \rceil$ and y_{\max} being the magnitude of the largest sub-band coefficient.

After initialization, the algorithm goes through sorting and refinement stages with respect to T . During the sorting phase, each coefficient in the LIP is compared with the threshold T , and the result of the comparison (a symbol being 0 or 1) is sent to the channel. If a coefficient exceeds T , then its sign is transmitted and its coordinate moved to the LSP. In a second phase of the sorting pass, each set having its root in the LIS is compared with T , and

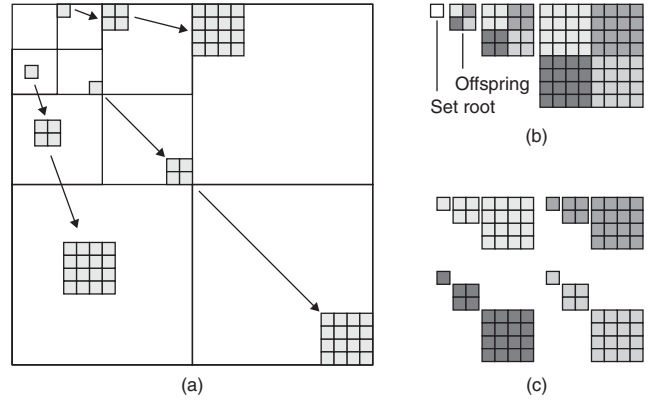

Figure 12: Formation of sets. (a) Sets and zerotrees within the wavelet tree; (b) set; (c) set of (b) partitioned into four subsets

if no coefficient exceeds T , then a zero is sent to the channel. If at least one coefficient within a set is larger than T , then a 1 is sent and the set gets subdivided into the four offspring and four smaller sets. The offspring are tested for significance, and their coordinates are moved to the appropriate list (LIP or LSP). The offspring coordinates are also used as roots for the four smaller sets. See Figures 12b and 12c for an illustration of set partitioning. The significance test and subdivision of sets are carried out until all significant coefficients with respect to T have been isolated. At the end of the procedure with threshold T , all coordinates of significant coefficients are stored in the LSP and their signs have been transmitted along with the sorting information required to identify the positions of the transmitted coefficients. In the next stage, the threshold is halved, and the accuracy of the coefficients in the LSP is refined by sending the information of whether a coefficient lies in the upper or lower half of the uncertainty interval. Then the next sorting pass with the new threshold is carried out and so on. The procedure is repeated until a bit budget is exhausted or the threshold falls below a given limit.

The SPIHT decoder looks at the same significance tests as the encoder and receives the answers to the tests from the bit stream. This allows the decoder to reconstruct the sub-band coefficients bit plane by bit plane. The reconstruction levels are always in the middle of the uncertainty interval. This means that if the decoder knows, for example, that a coefficient is larger than or equal to 2^k (with some k) and smaller than 2^{k+1} , it reconstructs the coefficient as 1.5×2^k . The bit stream can be truncated

at any point to meet a bit budget, and the decoder can reconstruct the best possible image for the number of bits received.

An interesting modification of the SPIHT algorithm called *virtual SPIHT* has been proposed by Khan and Ghanbari (2001). This coder virtually extends the octave decomposition until only three set roots are required in the LIS at initialization. This formation of larger initial sets results in more efficient sorting during the first rounds where most coefficients are insignificant with respect to the threshold. Further modifications include, for example, three-dimensional extensions for coding of video (Kim, Xiong, and Pearlman 2000).

Although EZW and SPIHT coding cater well to SNR embeddedness, they do not allow for spatial scalability in the sense that a given bit stream for an $M \times N$ image can be easily parsed into a bit stream for an image of size $(2^{-k}M) \times (2^{-k}N)$ with k being a positive integer. In addition, object-based access is not originally included. These limitations have been overcome by the highly scalable set partitioning algorithm of Danyali and Mertins (2004). This method uses separate lists for the different spatial resolution levels and creates a bit stream that is both SNR and resolution embedded. Higher resolution levels that are not required for a certain target resolution can be easily removed on the fly by a simple parser. Moreover, the method allows for the encoding of arbitrarily shaped objects.

Another efficient and progressive encoding scheme that does not exploit spatial significance trees is the so-called *embedded block coding with optimized truncation* (EBCOT) proposed by Taubmann (2000). This method first encodes blocks of wavelet-transform coefficients in a bit plane by bit plane manner, using a context-dependent arithmetic coding technique. This step results in independent embedded bit streams for each code block. During the individual encoding processes, points of the *rate-distortion* (RD) curves for each code block are determined and stored. In a second step, given an actual bit budget and the stored samples of the RD curves, the optimal bit allocations and thus the code-stream truncation points for the individual blocks are found through a postcompression rate-distortion optimization. By using this principle for several stepwise increasing budgets, a progressively layered code stream is generated. This is illustrated in Figure 13, which shows the formation of layers from the individual embedded code streams.

IMAGE COMPRESSION STANDARDS

A large number of image formats exists. The simplest one is the *bitmap* (BMP) format, which encodes the color components of an image in uncompressed form. The *tagged*

Figure 13: Formation of layered code stream from embedded code streams of individual code blocks

image file format (TIFF) is a container format that allows for the inclusion of various image formats. It is best known for its lossless mode (either uncompressed or losslessly compressed); a TIFF file may, however, also include a lossy-encoded JPEG image (see following). In the following, we will describe the most important formats that achieve significant compression or are widely used throughout the Internet.

GIF

The *graphics interchange format* (GIF) is a lossless image coding format based on the LZW algorithm. It became quite popular for encoding computer-generated images such as buttons on Web sites. GIF allows for interlacing the lines of an image in the order 0, 8, 16, ..., 4, 12, 20, ..., 2, 6, 10, ..., 1, 3, 5, 7, ..., which helps to see a reasonable approximation of the image earlier during transmission. GIF is limited to 256 different colors, so it is not well suited for natural images. Because of the licensing problems for the LZW algorithm mentioned earlier, GIF has been abandoned by some software developers who did not want to pay royalties; it has been replaced with the PNG format, which has been intentionally developed as a license-free coding method.

PNG

PNG stands for *portable network graphics* and is a losslessly compressed image format. It was designed as a license-free format that would also overcome some of GIF's limitations such as the low color depth. PNG uses a lossless compression method called *deflation* in combination with the prediction of actual pixel colors from previously seen colors. The deflation algorithm consists of LZ77, followed by a variable-length code. PNG allows for up to 48-bit color depth and offers a more sophisticated interlacing scheme than GIF. The interlacing in PNG is truly two-dimensional and yields a clearer low-resolution image earlier during transmission.

JPEG

JPEG is an industry standard for digital image compression of continuous-tone images developed by the Joint Photographic Experts Group, which is a group of experts nominated by leading companies, academia, and national standards bodies. JPEG was approved by the principal members of ISO and IEC JTC1 as an international standard (IS 10918-1) in 1992 and by the CCITT as recommendation T.81, also in 1992. It includes the following modes of operation (Wallace 1992): a sequential mode, a progressive mode, a hierarchical mode, and a lossless mode. In the following, we will discuss the so-called baseline coder, which is a simple form of the sequential mode that encodes images block by block in scan order from left to right and top to bottom. Image data are allowed to have 8-bit or 12-bit precision. The baseline algorithm is designed for lossy compression with target bit rates in the range of 0.25 to 2 bits per pixel (bpp). The coder uses blockwise DCT, followed by scalar quantization and entropy coding based on run-length and Huffman coding. The general

Figure 14: Zigzag scanning order in JPEG

structure is the same as in Figure 3. The color space is not specified in the standard, but mostly the YUV space is used with each component treated separately.

After the blockwise DCT (block size 8×8), scalar quantization is carried out with uniform quantizers. This is done by dividing the transform coefficients $y_{k,\ell}$, $k, \ell = 0, 1, \dots, 7$ in a block by the corresponding entries $q_{k,\ell}$ in an 8×8 quantization matrix and rounding to the nearest integer: $a_{k,\ell} = \text{round}(y_{k,\ell}/q_{k,\ell})$. Later in the reconstruction stage, an inverse quantization is carried out as $\hat{y}_{k,\ell} = q_{k,\ell} \cdot a_{k,\ell}$. Particular, perceptually optimized quantization matrices have been included in the standard as a recommendation, but they are not a requirement and other quantizers may be used. To obtain more flexibility, all quantization matrices are often scaled such that step sizes $q'_{k,\ell} = D \cdot q_{k,\ell}$ are used instead of $q_{k,\ell}$. The factor D then gives control over the bit rate.

The quantized coefficients in each block are scanned in a zigzag manner, as shown in Figure 14, and are then further entropy encoded. First, the DC coefficient of a block is differentially encoded with respect to the DC coefficient of the previous block (DPCM), using a Huffman code. Then the remaining sixty-three quantized AC coefficients of a block are encoded. The actual coefficient values are Huffman encoded together with the run of zeros from the last nonzero coefficient along the zigzag scanning pass using a two-stage Huffman coding technique with predefined codebooks. The special treatment of zero runs is used, because the occurrence of long stretches of zeros during the zigzag scan is quite likely and coding of individual zeros would be inefficient. If all remaining coefficients along the zigzag scan are zero, then a special end of block symbol is used.

JPEG-LS

JPEG-LS is a standard for lossless and near lossless compression of continuous-tone images (Joint Photographic Experts Group 1997). In the near lossless mode, the user can specify the maximum error ε that may occur during compression. Lossless coding means $\varepsilon = 0$. The performance of JPEG-LS for lossless coding is significantly better than the lossless mode in JPEG.

To achieve compression, context modeling, prediction, and entropy, coding based on Golomb-Rice codes are used. Golomb-Rice codes are a special class of Huffman codes for geometric distributions. The context of a pixel x is determined from four reconstructed pixels a, b, c, d in the neighborhood of x , as shown in Figure 15. Context

Figure 15: Context modeling in JPEG-LS

is used to decide whether x will be encoded in the run or regular mode.

The run mode (run-length coding) is chosen when the context determines that x is likely to be within the specified tolerance ε of the last encoded pixel. This may be the case in smooth image regions. The run mode is ended either at the end of the current line or when the reconstruction error for a pixel exceeds ε . To encode the run length, a modified Golomb-Rice code is applied.

The regular mode is used when, based on the context, it is unlikely that x lies within the tolerance ε of the previously encoded pixel. In this mode, a prediction for x is computed based on the three neighboring values a, b , and c according to

$$\hat{x} = \begin{cases} \min(a, b) & \text{if } c \geq \max(a, b) \\ \max(a, b) & \text{if } c \leq \min(a, b) \\ a + b - c & \text{otherwise.} \end{cases}$$

This predictor adapts to local edges and is known as a *median edge detection predictor*. In a second step, the prediction is corrected by a context-dependent term to remove systematic prediction biases. The difference between the bias-corrected prediction and the actual value is then encoded using a Golomb-Rice code.

JBIG

The acronym JBIG stands for Joint Bilevel Image experts Group, which is a group of nominees from industry, academia, and government bodies that is working on both ISO and ITU-T standards. JBIG targets the compression of bilevel images, or images that contain only two possible colors (e.g., black and white). When JBIG was created, the aim was to replace older bilevel facsimile standards such as the ITU-T Recommendations T.4 (MH, MR) and T.6 (MMR) with more efficient and flexible techniques.

JBIG has first developed the ISO/IEC 11544 (ITU-T T.82) standard (also known as JBIG1) for the compression of bilevel images. JBIG1 has been designed for lossless and progressive (i.e., lossy-to-lossless) coding, but its capabilities for lossy coding are quite limited.

To see how JBIG1 works, let us consider the encoding of a pixel in a page of digitized text. For such a bilevel image, given the knowledge of some neighboring pixels, one can often infer with high probability what the color of the actual pixel will be. For example, if all neighboring pixels are white, then the probability for the pixel being white will be high. This principle is used in JBIG1 to select one of several arithmetic coders that are optimized for different neighboring pixel configurations. In doing so, a better overall efficiency can be achieved than with a single arithmetic coder.

Figure 16: Neighborhood systems for the low-resolution layer in JBIG1

The neighborhood system used in JBIG1 for the low-resolution part is depicted in Figure 16. The pixels marked o and A are previously encoded ones, and the pixel marked X is the one to be encoded. The position of the pixel marked A is variable and can be chosen to capture some structure (such as vertical lines) in the image. With 10 neighboring pixels, there are $2^{10} = 1024$ different possible neighborhood pixel configurations, and each one yields a different probability for the pixel X to be black or white. Therefore, JBIG would select the best arithmetic coder from 1024 possible ones, depending on the neighborhood pattern.

In the progressive mode, the low-resolution pixels are included in the context for the high-resolution layer together with previously encoded high-resolution pixels. There are four different neighborhood templates with 10 pixels each, so 4096 different neighborhood patterns exist. Consequently, the algorithm selects one of 4096 possible arithmetic coders to encode the pixel.

More recently, a new recommendation known as JBIG2 (lossy and lossless coding of bilevel images) has been published as ISO/IEC 14492 and ITU T.88. It directly targets lossless, lossy, and lossy-to-lossless bilevel image compression. In addition to quality-progressive coding, JBIG2 also includes content-progressive coding, which means that different types of image data are successively added (for example, first text, then halftones). Different compression methods and context models may be applied for text, halftones, and other binary image content. There are a number of fixed templates like in JBIG1, but there exist also adaptive templates for better capturing document structures. Moreover, JBIG2 handles multipage documents in an explicit way.

JPEG 2000

The JPEG 2000 standard is a new standard for still image compression that provides a series of functionalities that were not addressed by the original JPEG standard (Christopoulos, Skodras, and Ebrahimi 2000; Joint Photographic Experts Group 2000). The main features of JPEG 2000 are as follows:

- It can code any type of image (bilevel, continuous tone, multicomponent) with virtually no restriction on image size.
- It handles a wide range of compression factors from 200:1 to lossless.
- It offers progressive transmission by accuracy (signal-to-noise ratio) and spatial resolution.
- It handles lossless and lossy compression within one bit stream.
- It uses random code stream access.

- It demonstrates robustness to bit errors.
- It uses region of interest with improved quality.

To be backwardly compatible with JPEG, the new JPEG 2000 standard includes a DCT mode similar to JPEG, but the core of JPEG 2000 is based on the wavelet transform. JPEG 2000 is being developed in several stages, and in the following we refer to the baseline JPEG 2000 coder as specified in part 1 of the standard. The structure of the baseline JPEG 2000 coder is essentially the one in Figure 3, with the wavelet transform of Figure 8 as the decorrelating transform. To allow for processing of extremely large images on hardware with limited memory resources, it is possible to divide images into tiles and carry out the wavelet transform and compression for each tile independently. The wavelet filters specified are the Daubechies 9-7 filters (Antonini et al. 1992) for maximum performance in the lossy mode and the 5-3 integer-coefficient filters (LeGall and Tabatabai 1988) for an integrated lossy-to-lossless mode. Boundary processing is carried out using the extension scheme for odd-length filters with whole-sample symmetry discussed above.

The quantization stage uses simple scalar quantizers with a dead zone around zero. The quantizer index a that results from quantizing a variable x with step size q is given by

$$a = \begin{cases} \text{sign}(x) \left\lfloor \frac{|x|}{q} + \xi \right\rfloor, & \frac{|x|}{q} + \xi > 0 \\ 0, & \text{otherwise} \end{cases}$$

The value of ξ is set to $\xi = 0$ in part 1 of the JPEG 2000 standard, and it is variable with $\xi \in [-1, 1)$ in part 2. Given the quantizer index a , the reconstructed value \hat{x} is computed as

$$\hat{x} = \begin{cases} \text{sign}(a) \left(|a| - \xi + \delta \right) q, & a \neq 0 \\ 0, & a = 0 \end{cases}$$

The value for δ satisfies $0 \leq \delta < 1$ and is typically chosen as $\delta = 0.5$ so that the reconstructed value lies in the middle of the uncertainty interval. The step sizes for the quantizers are determined from the dynamic ranges of the coefficients in the different sub-bands. In the lossless mode where all sub-band coefficients are integers, the step size is one. The quantized coefficients within each sub-band are then grouped into code blocks that are encoded separately. Independent compression of sub-bands in code blocks is the key to random code-stream access and simple spatial resolution scalability. Only the code blocks referring to a certain region of interest at a desired spatial resolution level of the wavelet tree need to be transmitted or decoded. SNR scalability is achieved through the layer technique described earlier for the EBCOT method.

To demonstrate the performance of JPEG 2000 and provide a comparison with the older JPEG standard, Figure 17 shows some coding examples. One can see that JPEG produces severe blocking artifacts at low rates (in this example, 0.5 bpp) whereas JPEG 2000 tends to produce slightly blurry images. At the higher rate of 2 bpp, both

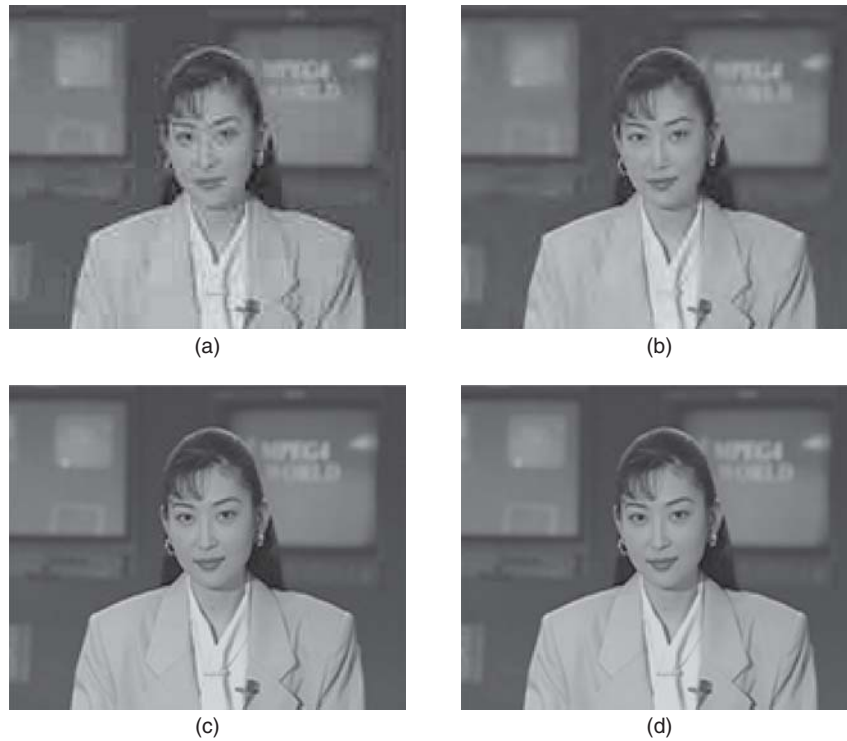

Figure 17: Coding examples (144×176 pixels). (a) JPEG at 0.5 bpp; (b) JPEG 2000 at 0.5 bpp; (c) JPEG at 2 bpp; (d) JPEG 2000 at 2 bpp

standards yield good quality images that can hardly be distinguished by the human eye, but JPEG 2000 still has the better signal-to-noise ratio.

Part 2 of the standard includes optional techniques such as trellis-coded quantization (Kasner, Marcellin, and Hunt 1999), which are not required for all implementations. Part 3 addresses Motion JPEG 2000 and defines a file format for storing sequences of images and gives support for associated audio. However, unlike in video coding, each frame is coded independently using JPEG 2000. Applications of this technique are, for example, the storage of video clips using digital still cameras, high-quality frame-based video recording and editing, digital cinema, and medical and satellite imagery. Part 4 addresses conformance and testing, and part 5 contains a reference software. Part 6 describes a file format for document imaging that can be used for storing multipage documents with many objects per page. Part 7 has been abandoned. Part 8 addresses security aspects and ownership protection. Part 9 defines interactive protocols and tools for supporting image and metadata delivery in the context of a networked environment. The main component of part 9 is a client/server protocol (JPIP) that may be implemented on top of HTTP and is designed to handle several different formats for the image data such as complete JPEG or JPEG 2000 files and incremental streams that take full advantage of JPEG 2000's scalability features. Part 10 addresses genuine volumetric image compression rather than frame-wise coding as in Motion JPEG 2000. Part 11 targets wireless multimedia applications, and part 12 is a joint initiative of JPEG and MPEG that aims to create a common file format for future applications using timed sequences of media data.

CONCLUSION

This chapter has reviewed general concepts and standards for still-image compression. We started by looking at theoretical foundations of data compression and then discussed some of the most popular image compression techniques and standards. We saw that different algorithms are used for different types of images. For example, computer-generated images have other properties than natural images and allow for different compression techniques. Moreover, bilevel images require other algorithms than gray-scale and color images. This makes clear that there is and will be a large variety of tools and techniques for still-image compression. Regarding natural images, from today's point of view the diverse functionalities required by many multimedia applications are best provided by coders based on the wavelet transform. As demonstrated in the JPEG 2000 standard, wavelet-based coders even allow the integration of lossy and lossless coding, which is a feature that is highly desirable for applications such as medical imaging where the highest quality is needed. The compression ratios obtained with lossless JPEG 2000 are in the same order as the ones obtained with dedicated lossless methods. However, because lossless coding based on the wavelet transform is still in an early stage, we may expect even better integrated lossy and lossless wavelet-based coders to be developed in the future. In addition to improving on lossless coding, the current research challenges include achieving better error resilience, more flexible object-based access and manipulation, and the incorporation of more up-to-date knowledge of human perception in lossy compression.

GLOSSARY

Differential pulse code modulation (DPCM): A coding technique in which prediction errors are quantized and coded.

Discrete cosine transform (DCT): A transform that is used to decorrelate image blocks.

Discrete wavelet transform (DWT): A multiresolution analysis method that is used in image compression to decorrelate image data.

Embedded block coding with optimized truncation (EBCOT): A technique to generate layered codestreams.

Embedded zerotree wavelet coding (EZW): A wavelet-based coding technique that exploits relationships between wavelet coefficients at different scales.

Karhunen-Loève transform (KLT): A decorrelating transform, also known as principal component analysis.

Lempel-Ziv-Welch algorithm (LZW): A universal coding method.

Pulse code modulation (PCM): A coding technique where signal samples are quantized and encoded separately and independently.

Quantization: The assignment of a discrete symbol to a range of input values.

Set partitioning in hierarchical trees (SPIHT): A wavelet-based coding technique that exploits relationships between wavelet coefficients at different scales.

Vector quantization (VQ): A coding technique where signal samples are quantized and encoded jointly.

INTRODUCTION

What Is Video Compression?

Video compression is a method of reducing the amount of digital data used to represent a sequence of images that normally vary in time and are intended to portray motion.

This chapter focuses on principles of video compression in a cumulative presentation that follows from chapters in this volume on information theory, data compression, image compression, high-definition television (HDTV), and error correction. The presentation intersperses practical examples with just-in-time theoretical analysis.

In this chapter, the first section introduces and demonstrates the need for video compression. The second, third, and fourth sections describe and discuss standards developed by the Joint Photographic Experts Group (JPEG), the International Telecommunication Union (ITU), and the Moving Picture Experts Group (MPEG). The fifth section refers to proprietary codecs developed by Microsoft, Real Networks, On2 Technologies, and Euclid Discoveries, including a proprietary codec standardized by the Society of Motion Picture and Television Engineers (SMPTE). The last section before the conclusion provides a simple evaluation of commercially available codecs for real-time communications.

Why Do We Need Video Compression?

Many people would like to hold conversations over video telephone systems, such as the *freedom of mobile*

multimedia access (FOMA) system developed by NTT DoCoMo (Tachikawa 2003). Other people would like to watch digital movies on their cable television systems, store and retrieve video on demand from high-density optical disks, or videoconference with business partners. The required data rate (frame rate \times frame size \times color depth) usually exceeds the available communications bandwidth, a problem for which video compression provides a technical solution.

Visual Inspection

As a practical example, Figure 1 shows images of frames numbered 1231 to 1233 from *The Emotion of Space* movie (National Aeronautics and Space Administration 2001), indicating a scene change at frame 1232 and motion sequence from frames 1232 to 1233.

The 3219 frames of this movie, which is 215 seconds in length, include monochrome still images, historic monochrome video, color video with rapidly moving objects, animation sequences, human faces, and crowd scenes. The movie has frame size 320×240 pixels, 24-bit color depth (8 bits each for the red, green, and blue channels), and an average frame rate of 15 frames per second (fps). Real-time transmission without compression requires 27.7 megabytes per second (Mbps), not considering the audio tracks. This bit rate is far above the capacity of a typical 384-kbps FOMA video telephone connection or 1.5-Mbps digital television channel under optimal conditions.

Visual inspection of Figure 1 reveals considerable overlap between frames 1232 and 1233 but discontinuous change of scene between frames 1231 and 1232 (a likely

Figure 1: Images of frames 1231 to 1233 from the NASA movie *The Emotion of Space* showing scene change at frame 1232 and motion sequence from frames 1232 to 1233

result of editing). The space suit color (not shown in these gray-scale images) contrasts well with the background, which indicates *spectral redundancy*. Each frame depicts a small number of recognizable visual objects, which indicates local *spatial redundancy*. The motion of the astronauts indicates *temporal redundancy*. The viewer focuses attention on the motion of the astronauts and the expressions on their faces, which indicates *psychovisual redundancy* (i.e., redundancy related to human perception of vision).

Accordingly, this chapter shows how video compression methods solve the problems of communicating *The Emotion of Space* over bidirectional videophones by reducing spectral, spatial, temporal, and psychovisual redundancies while also addressing rate control, scalability, error resilience, and applications. In addition, the chapter shows how video compression methods solve problems in distributing digital cinema movies, transmitting and receiving NASA's Mars Exploration Rover image sequences, storing and retrieving high-definition television sequences, and videoconferencing with business partners.

Video Compression

Video compression trades communications bandwidth and media storage space for picture quality and processor cycles.

Video compression methods are described as *lossless*, *lossy*, *progressive*, or *hybrid*. Unlike lossless methods, which are exact and reversible, lossy methods are approximate and irreversible. The term *lossy* arose by analogy with a concept familiar to electrical engineers: the dissipation of electrical energy as heat in the transmission of power. Quoting Shannon (1948), "The fundamental problem of communication is that of reproducing at one point either exactly or approximately a message selected at another point." In multidisciplinary environments, the terms *exact* and *approximate* are often more acceptable than the terms *lossless* and *lossy*. *Progressive* methods provide a sequence of approximations that may become exact. *Hybrid* methods preserve picture quality by exactly coding residuals from compressed approximations. This chapter points out lossless, lossy, progressive, and hybrid methods when appropriate.

Remotely sensed images (such as radar and satellite images) are often noisy. The image noise carries information about sensor characteristics, background, and unresolved images. Although researchers frequently state that

image noise is incompressible, identifying noise process parameters or reporting noise summary statistics conveys information that can be used to reconstruct the noise.

Rate-Distortion Bound

For a small reduction in picture quality (distortion), lossy methods often yield far greater reduction in data rate than quality-preserving lossless methods. The *Shannon rate-distortion bound* refers to the minimum average bit rate required to encode a data source for a given average distortion; it is useful for exploring the limits of compressibility for a *memoryless image source*, which selects each pixel's luminance value independently of all of the others (see "Information Theory" and "Image Compression"). With perfect reconstruction of data, the bit rate at zero distortion is equal to the source entropy, a measure of the information contained in the source. In practice, many researchers compare the effectiveness of video compression algorithms by plotting empirically determined quality measures as a function of observed bit rate for a specified set of video sequences. Almost invariably, the observed video quality improves with increased bit rate.

Equation 1 defines Shannon's entropy H for an image in units of *bits per pixel* (bpp), where $p(I)$ is the probability of pixel value I .

$$H = - \sum_{I=0}^{2^m-1} p(I) \log_2 p(I) \quad (1)$$

The observed histogram of pixel values over all video sequence frames determines the observed Shannon's entropy.

Video Quality Metrics

Let each frame have $N \times M$ pixels with bit depth m . Let the pixel value at location (i, j) in frame k be $I(i, j, k)$ for the original frame and $\hat{I}(i, j, k)$ for the reconstructed frame. To measure video quality, Equation 2 exhibits the *mean square error* and *peak signal-to-noise ratio* (PSNR) for a video sequence of K frames.

$$MSE = \frac{1}{NMK} \sum_{k=1}^K \sum_{j=1}^N \sum_{i=1}^M [I(i, j, k) - \hat{I}(i, j, k)]^2 \quad (2)$$

$$PSNR = 20 \log_{10} \left(\frac{2^m - 1}{\sqrt{MSE}} \right)$$

Although many researchers use PSNR as a measure of video quality, measuring the quality of a video sequence reconstructed from compressed imagery is an application-dependent task.

Subjective evaluation requires a group of human observers—preferably not experts in image quality assessment—to view and rate video quality in terms of a scale of impairments that range from “imperceptible” to “very annoying.” The BT.500-11 standard developed by the radiocommunication sector of the International Telecommunications Union titled “Methodology for the Subjective Assessment of the Quality of Television Pictures” (ITU-R 2002), recommends a specific system and prescribes viewing conditions, range of luminance presented to the viewer panel, number and experience of viewers, monitor contrast, selection of test materials, and suggested processes for evaluating test results. The *double stimulus impairment scale* (DSIS) and the *double stimulus continuous quality scale* (DSCQS) are particularly noteworthy. Subjective tests are costly and not highly reproducible. Two standards set by the American National Standards Institute (ANSI) are of value here: T1.801.01-1995 (ANSI 1995) provides a set of test scenes in digital format while T1.801.02-1996 (ANSI 1996) provides a dictionary of commonly used video quality impairment terms.

Objective evaluation techniques include the ANSI T1.803.03-2003 (Annex A) standard, which lists a set of objective test criteria used to measure video quality in one-way video systems, applying objective tests closely related to known features of the *human visual system* (HVS). A video quality metric software implementation of the Annex A standard is currently available from the Institute for Telecommunication Sciences, which is the research and engineering branch of the U.S. government’s National Telecommunications and Information Administration.

Lossless Entropy Coder

Consider independently compressing each frame of the 3219 RGB video frames of *The Emotion of Space* depicted in Figure 1. Recall from “Data Compression” that a lossless entropy coder converts a sequence of input symbols into a sequence of bits such that the average number of bits approaches the entropy of the symbols. Figure 2a depicts a lossless entropy encoder, and Figure 2b depicts a lossless entropy decoder corresponding to Figure 2a. An encoder and corresponding decoder together form a *codec*.

The lossless entropy coder selected for this example is a *Witten-Neal-Cleary adaptive arithmetic coder* according to the implementation developed by Witten et al. (1987). This arithmetic coder represents a message as an interval of real numbers between zero and one. Successive symbols of the message reduce the interval, increasing the number of bits required to represent the interval according to symbol probabilities generated from a model updated as the symbols are encoded.

Lossless Entropy Coder Performance

Figure 3 shows the result of compressing all 3219 frames of *The Emotion of Space* with the Witten-Neal-Cleary coder together with the Shannon’s entropy according to Equation 1. The Figure also indicates the arithmetically encoded bit rate and Shannon’s entropy according to Equation 3 for each frame, expressed in bpp:

$$\text{bit rate} = 24 \bullet \left(\frac{\text{compressed frame size in bits}}{\text{original frame size in bits}} \right) \text{bits-per-pixel} \quad (3)$$

Horizontal lines indicate the movie average bit rate and Shannon’s entropy. The arithmetically encoded bit rate and Shannon’s entropy are highly variable, which is appropriate for the highly variable information content including scene changes and fades. The average arithmetically encoded bit rate is 18.68bpp, which is approximately 4.918bpp above the average Shannon’s entropy of 13.76bpp. Encoding *The Emotion of Space* at approximately 384kbps requires $24 \text{bpp} \times (384 \text{kbps} / 27.7 \text{Mbps}) = 0.333 \text{bpp}$.

Motion DCT Codec

To further illustrate the above concepts, consider independently compressing each of the 3219 RGB video frames of *The Emotion of Space* with a simplified block transform coder based on the *discrete cosine transform* (DCT) and a lossless entropy coder. Figure 4 shows a block diagram for an initial version of this simple coder, reminiscent of the well-known baseline image coder standardized by the JPEG.

Each frame has $N \times M$ pixels for each color component. If $N = 0 \pmod{B}$ and $M = 0 \pmod{B}$, then each frame can be covered without padding by contiguous nonoverlapping blocks of $B \times B$ pixels.

Figure 2: Lossless entropy (a) encoder and (b) decoder

Figure 3: Arithmetic coding (bpp) and Shannon's entropy versus frame number for *The Emotion of Space* (NASA, 2001)

Figure 4: Motion DCT encoder

The DCT is widely used for video coding because the transform coefficients are independent of frame content and effectively reduce spatial redundancy by decorrelating the pixel values. For highly correlated adjacent pixels, the DCT performs nearly as well as the optimal Karhunen-Loève transform, which has coefficients laboriously calculated from the pixel values of each frame.

Equation 4 gives the two-dimensional separable DCT of the pixel values $I(x, y)$ for pixels at block coordinates (x, y) where $x \in [0, \dots, B-1]$, $y \in [0, \dots, B-1]$:

$$DCT(m, n) = \frac{1}{\sqrt{2B}} C(m)C(n) \sum_{x=0}^{B-1} \sum_{y=0}^{B-1} I(x, y) \cos\left[\frac{(2x+1)m\pi}{2B}\right] \cos\left[\frac{(2y+1)n\pi}{2B}\right] \quad (4)$$

$$C(i) = \begin{cases} \frac{1}{\sqrt{2}}, & i = 0 \\ 1, & i > 0 \end{cases}$$

Approximating the coefficients $DCT(m, n)$ by uniform scalar quantization, Equation 5 shows how to obtain the quantized coefficients $QDCT(m, n)$ by rounding and division with positive integer quantization parameter Q :

$$QDCT(m, n) = \text{round}\left(\frac{DCT(m, n)}{Q}\right) \quad (5)$$

The decoder reconstructs coefficients DCT' according to Equation 6:

$$DCT'(m, n) = Q \bullet QDCT(m, n) \quad (6)$$

Equation 7 shows how to reconstruct image blocks $\bar{B}(x, y)$ from the quantized coefficients $QDCT(m, n)$. Note that rounding ensures lossy compression even when the quantization parameter Q is set to unity.

$$\bar{B}(x, y) = \frac{1}{\sqrt{2N}} \sum_{m=0}^{N-1} \sum_{n=0}^{N-1} C(m)C(n)QDCT(m, n) \cos\left[\frac{(2x+1)m\pi}{2N}\right] \cos\left[\frac{(2y+1)n\pi}{2N}\right] \quad (7)$$

$$C(i) = \begin{cases} \frac{1}{\sqrt{2}}, & i = 0 \\ 1, & i > 0 \end{cases}$$

The *minimum coded unit* (MCU) is the minimum amount of image data that a coder can code. For noninterleaved image data, Equations 4 and 7 indicate that the motion DCT coder can compress or decompress as little as one $B \times B$ -pixel block. Hence, the motion DCT coder can provide easy access to compressed image blocks for nonlinear editing together with a low level of latency (delay) for encoding and decoding.

A lossless entropy coder encodes the quantized coefficients $QDCT(m, n)$. The lossless entropy coder selected

Figure 5: Motion DCT decoder

Figure 6: Motion DCT average and standard deviation bit rate (bpp) versus quantization parameter for *The Emotion of Space* (3219 frames)

for this example is the Witten-Neal-Cleary adaptive arithmetic coder described above.

Figure 5 shows a block diagram for an initial version of a simple decoder that decodes the compressed frames into quantized coefficients $QDCT(m, n)$ with an entropy decoder according to Witten et al. (1987). A transform decoder restores image blocks from the quantized coefficients according to Equation 5.

Motion DCT Performance

Figure 6 shows the observed average and standard deviation in bpp versus quantization parameter for 3219 frames of *The Emotion of Space* encoded by the motion DCT encoder implemented in MATLAB and the C programming language. Quantization parameter values ranging from 2 to 256 result in bit rates ranging from 6.64 to 0.651 bpp.

Figure 7 shows a panel of gray-scale images representing color frame 1232 of *The Emotion of Space* compressed by the motion DCT coder to bit rates (a) 6.63, (b) 4.74, (c) 3.35, (d) 2.36, (e) 1.70, (f) 1.26, (g) 0.927, and (i) 0.651 bpp. These images illustrate lossy, progressive compression with quantization parameters $Q = 2, 4, 8, 16, 32, 64, 128$, and 256 corresponding to the above bit rates.

Figure 8 shows the objective video quality versus bit rate (bpp) measured by the PSNR metric according to Equation 2 and the *video quality metric* (VQM) software implementation of the T1.803.03-2003 Annex A standard (ANSI 2003). The VQM is measured on the aforementioned DSIS (5 = imperceptible, 4 = perceptible but

not annoying, 3 = slightly annoying, 2 = annoying, and 1 = very annoying).

The VQM objective video quality assessment agrees substantially with the subjective video quality assessment described above. Within the visually acceptable range of observed VQM values (approximately 3 to 5 on the DSIS), the observed PSNR metric values range from approximately 30 to 60 dB.

In summary, the motion DCT codec illustrates the principles of spatial redundancy reduction but does not achieve the goal of communicating *The Emotion of Space* over bidirectional videophones at a near constant bit rate of 384 kbps with acceptable video quality. Several standardized video codecs perform better than the motion DCT codec.

Standards

Standards are requirement documents that indicate detail only in areas of agreement between standards participants (who are often competitors). Practicing the standards requires proprietary technology, for which some patent holders have agreed to provide licenses on reasonable and nondiscriminatory terms.

Note that the standards typically specify reference decoders, not encoders. Although this chapter presents encoding techniques, encoders typically comply with the standard if the standard reference decoder can decode the bit stream they produce. This approach to standardization maximizes flexibility and innovation while ensuring a modicum of interoperability between implementations.

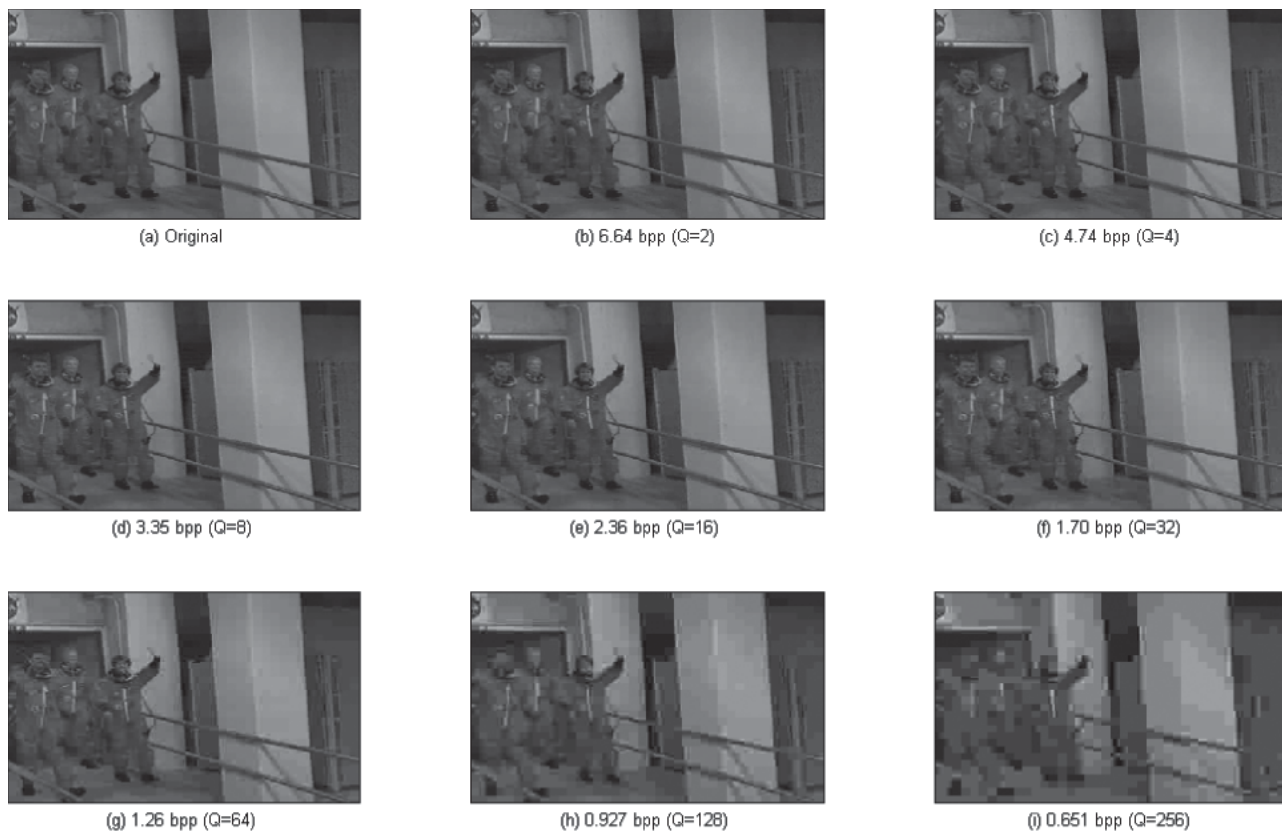

Figure 7: Panel of gray-scale images representing color frame 1232 of *The Emotion of Space* compressed by the Motion DCT coder to bit rates (b) 6.64, (c) 4.74, (d) 3.35, (e) 2.36, (f) 1.70, (g) 1.26, (h) 0.927, and (i) 0.651 bpp

Figure 8: PSNR and video quality metric versus bit rate (bpp) for a 30-second duration of *The Emotion of Space*, frames 1230 to 1679

JPEG CODECS

Motion JPEG—although never standardized—derives from the baseline JPEG standard for compression and coding of continuous-tone still images, 10918-1:1994 (ISO/IEC 1994).

The baseline JPEG standard encodes images with an arbitrary number of color components, comprising data samples having precision ranging from two to sixteen

bits. This standard supports four encoding modes: sequential DCT-based, progressive DCT-based, lossless, and hierarchical.

Motion JPEG-LS (also never standardized) derives from the JPEG standard for lossless and near-lossless compression of continuous tone still images, ISO/IEC 14495-1:1999(E). This standard improves and extends methods for baseline JPEG lossless encoding.

Part 3 of the JPEG 2000 standard for the JPEG 2000 image-coding system, 15444-3 (ISO/IEC 2002), standardizes Motion JPEG 2000. Motion JPEG 2000 is the most efficient, compressive, and flexible JPEG codec to date and so forms the primary topic of this section.

Spectral Domain

Motion JPEG and Motion JPEG-LS support an arbitrary number of color components without recommending or mandating any color space for spectral compression, although the JPEG standard cites an example based on a color space with luminance and chrominance color components.

Motion JPEG 2000 derives spectral compression from Parts 1 and 2 of the current JPEG 2000 standard, 15444-1 and 15444-2 (ISO/IEC, 2004a, 2004b). JPEG 2000 transforms image colors to reduce spectral redundancy. The *human visual system* (HVS) is typically more sensitive to changes in brightness than color, with peak color sensitivity to green. Accordingly, JPEG 2000 supports color transformation of images in the RGB color space to the $YCbCr$ color space given by Equation 8, where Y denotes image brightness signal (luma) while C_r and C_b denote red and blue color difference signals (chroma), respectively. A downsampling filter typically reduces the resolution of both C_r and C_b components by a factor of two in both horizontal and vertical directions:

$$\begin{bmatrix} Y \\ C_r \\ C_b \end{bmatrix} = \begin{bmatrix} 0.299 & 0.587 & 0.114 \\ -0.1688 & -0.3313 & 0.5 \\ 0.5 & -0.4187 & -0.08131 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (8)$$

In addition to the $YCbCr$ color space above, JPEG 2000 supports an integer *reversible color transform* (RCT) given by Equation 9, where V_1 denotes the luma signal, while V_2 and V_3 denote chroma signals, respectively:

$$\begin{aligned} V_1 &= \left\lfloor \frac{1}{4}(R + 2G + B) \right\rfloor \\ V_2 &= B - G \\ V_3 &= R - G \end{aligned} \quad (9)$$

To preserve reversibility, if any image component is unsigned, JPEG 2000 Part 1 Annex G specifies shifting the level of the unsigned component with depth $bits$ by subtracting 2^{bits-1} and storing the transformed values at one-bit greater precision than the original component.

JPEG 2000 Part 2 supports additional color spaces, such as Commission Internationale de l'Éclairage (CIE) XYZ tri-stimulus color values, together with color transforms for spectral decorrelation of multiple component images, which are often required by scientific and medical applications.

Reversible Color Transform

Figure 9 shows (a) red, (b) green, and (c) blue components of frame numbered 1232 from *The Emotion of Space* together with luma V_1 (d) and chroma V_2 (e), V_3 (f) components, following a reversible color transform from RGB to RCT color space.

To measure the effectiveness of color decorrelation, Equations 10 and 11 compare the covariance of samples between frame 1232 color components $\tilde{\mathbf{R}}_{RGB}$ (before) and $\tilde{\mathbf{R}}_{RCT}$ (after) transformation from RGB to RCT color space.

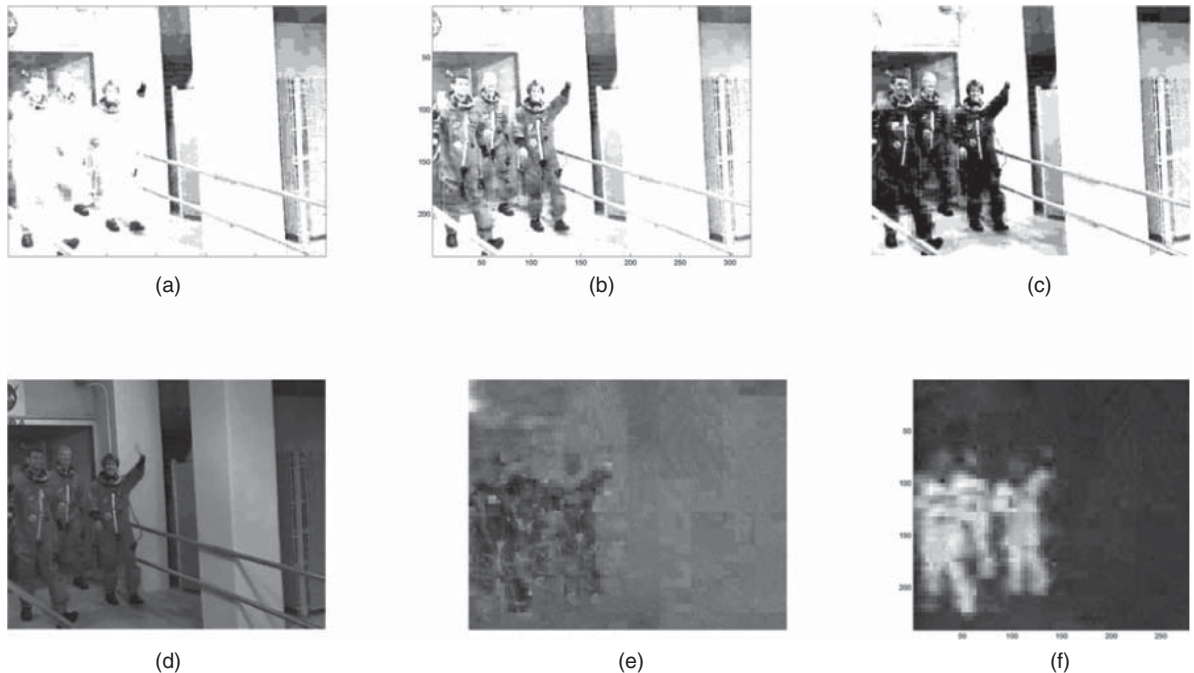

Figure 9: (a) red (b) green (c) blue (d) luma (e) chroma V_2 , and (f) chroma V_3 components of frame numbered 1232 from *The Emotion of Space*

$$\begin{aligned}\tilde{\mathbf{R}}_{RGB} &= 1000^* \begin{bmatrix} 1.573 & 1.334 & 1.303 \\ 1.334 & 1.886 & 2.041 \\ 1.303 & 2.041 & 2.279 \end{bmatrix} \\ \tilde{\mathbf{R}}_{RCT} &= 1000^* \begin{bmatrix} 1.719 & 0.1293 & -0.4010 \\ 0.1293 & 0.0842 & -0.1866 \\ -0.4010 & -0.1866 & 0.7900 \end{bmatrix}\end{aligned}\quad (10)$$

$$G_{color} = \frac{\sum_{n=1}^3 \tilde{\mathbf{R}}_{RGB}^2(n, n)}{\sum_{n=1}^3 \tilde{\mathbf{R}}_{RCT}^2(n, n)} = 10 \log_{10} \left(\frac{5.738}{2.213} \right) = 3.449 \text{ dB}\quad (11)$$

The transformation from RGB to RCT color space provides 3.449dB variance gain by substantially reducing correlation between color components.

Spatial Domain

Motion JPEG

The frequency distribution of DCT AC coefficients, as determined by Equation 4 for $m > 0$ and $n > 0$, is often described by a Laplacian (symmetric exponential) distribution. The DC coefficients ($m = 0, n = 0$) are typically distributed differently from the AC coefficients with relatively high block-to-block correlation. The fraction of nonzero-quantized AC coefficients often varies as a mild power law with average bit rate.

The JPEG committee recommended different treatments for DC and AC coefficients because of the high block-to-block correlation for DC coefficients and that quantization clears many AC coefficients. A Huffman or arithmetic lossless entropy coder encodes the transform coder output. The transform coder emits the difference between the DC coefficients for the current and previous blocks in row major order. As shown in Figure 10, the transform coder scans AC coefficients in zigzag order from the coefficient labeled 1 to the coefficient labeled

63 to increase the run length of zeros, which it identifies and codes efficiently.

The JPEG committee selected the 8×8 -pixel block size for transform coding, a decision practical at that time. A full frame block size would have reduced blocking impairments at the expense of increased computational resource. Operating in a hierarchical mode, a 4×4 -pixel block size would more likely than not have reduced impairments at the edges of visual objects.

Distribution of DCT Coefficients

Recalling the Motion DCT coder described above, Figure 11 shows the frequency distribution of discrete transform AC coefficients for Motion DCT *The Emotion of Space* as determined by Equation 4 for $m > 0$ and $n > 0$. Let y denote the frequency and x denote the value of the DCT AC coefficient. A Laplacian (symmetric exponential) distribution $y = a \exp - |x/b|$ where $a = 1.27 \cdot 10^8$, $b = 6.84$ fits this distribution with coefficient of determination $r^2 = 0.854$ for all RGB color components. For DC coefficients, the observed block-to-block correlation is $(74 \pm 18\%, 75 \pm 18\%, 58 \pm 36\%)$ for the red, green, and blue color components, respectively.

Figure 12 shows the fraction of nonzero-quantized AC DCT coefficients versus average bit rate (bpp) for the

0	2	5	9	14	20	27	35

Figure 12: Fraction of nonzero quantized DCT coefficients versus average bit rate (bpp) for *The Emotion of Space*

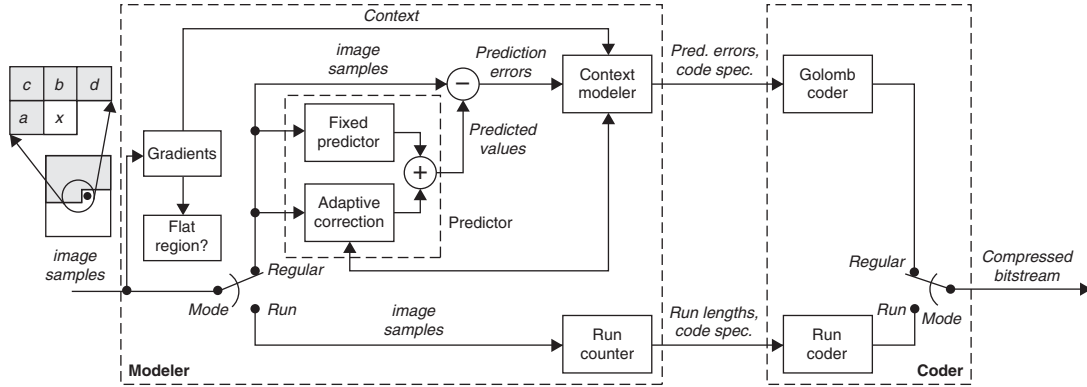

Figure 13: JPEG-LS block diagram after Weinberger et al. 1999

NASA movie and Motion DCT coder. Let y denote the fraction of nonzero-quantized DCT coefficients and x denote the average bit rate (bpp). A power curve $y = a^{bx}$ fits the data for all RGB color components, where $a = 0.0224 \pm 0.00037$ and $b = 1.37 \pm 0.0095$ with coefficient of determination $r^2 = 0.999$.

Whereas Figures 11 and 12 illustrate distributions observed for the motion DCT encoder, the corresponding distributions for generic transform coders often take these forms.

Quantization Matrices

The JPEG standard generalizes Equations 5 and 6 to Equations 12 and 13 by quantizing each AC coefficient separately in terms of a quantization matrix $Q(m, n)$ where $m, n \in [1, \dots, 7]$. The matrix allows an encoder to allocate bits between sub-bands:

$$QDCT(m, n) = \text{round} \left(\frac{DCT(m, n)}{Q(m, n)} \right) \quad (12)$$

$$DCT'(m, n) = Q(m, n) \bullet QDCT(m, n) \quad (13)$$

Note that the JPEG standard does not mandate specific tables for quantization, Huffman encoding, or arithmetic encoding, and it provides a default table only for arithmetic encoding. To decode a JPEG-compliant bit stream, the encoder tables must be available in the bit stream or from a separate source.

Motion JPEG-LS. Motion JPEG-LS provides hybrid lossless and near-lossless coding without using transforms. The current (1999) version is based on a low-complexity encoder termed LOCO-I (Weinberger et al. 1999).

Figure 13 shows the JPEG-LS block diagram and an image data sample (marked by x) in the context of its reconstructed nearest neighbors (a, b, c, d), whose pixel values the encoder combines to form a set of selectable linear predictors of x . Equation 14 gives the fixed predictor denoted by \hat{x}_{MED} , in terms of the pixel values a, b and c :

$$\hat{x}_{MED} = \begin{cases} \min(a, b) & \text{if } c \geq \max(a, b) \\ \max(a, b) & \text{if } c \leq \max(a, b) \\ a - b + c & \text{otherwise} \end{cases} \quad (14)$$

The fixed predictor \hat{x}_{MED} is the median of three fixed predictors, a , b , and $a + b - c$, and it tends to pick b when there is a vertical visual edge to the left of the current location, a , when there is a horizontal visual edge above the current location, and $a + b - c$, when no edge is detected. The JPEG-LS standard assumes that the integer context-dependent prediction residuals $\varepsilon = x - \hat{x}_{MED}$ follow the normalized biased Laplacian distribution with decay rate θ and bias $\mu = R - s$, $R = |\mu|$, $0 \leq s < 1$, given by Equation 15 with normalization factor denoted by $C(\theta, s)$:

$$P(\theta, \mu) = C(\theta, s) \theta^{|\varepsilon - R + s|}, \varepsilon = 0, \pm 1, \pm 2, \dots, \quad (15)$$

$$C(\theta, s) = (1 - \theta) / (\theta^{1-s} + \theta^s)$$

The adaptive correction shown in Figure 13 subtracts a low-complexity estimate of R , the integer part of the bias, from the prediction residuals. Equation 16 gives the distribution of residuals after adaptive correction:

$$P(\theta, s) = C(\theta, s) \theta^{|\varepsilon + s|}, \varepsilon = 0, \pm 1, \pm 2, \dots, \quad (16)$$

The context modeler in Figure 13 partitions the triplet of pixel value differences $\mathbf{g} = \{d - b, b - c, c - a\}$ into a fixed number of equiprobable regions. The run coder then codes the partitioned prediction residuals with a run-length code that the Golomb coder codes with a near-optimal entropy code.

In the near-lossless mode, the JPEG-LS encoder controls the maximum absolute error between a reconstructed image component and the corresponding value in the original image by quantizing prediction residuals.

Motion JPEG 2000. Figure 14 shows a block diagram for a Motion JPEG 2000 encoder, while Figure 15 shows a block diagram for the corresponding decoder.

“Image Compression” addresses wavelet transforms together with JPEG 2000 tier-1 and tier-2 codecs (see Taubman and Marcellin 2001).

Motion JPEG 2000 derives scalability of image size, bit rate, and quality from Part 1 of the JPEG 2000 standard. Spatial transforms recommended by JPEG 2000 include reversible 5/3 tap and irreversible 9/7 tap wavelets. Quantization of wavelet coefficients is a mechanism for lossy compression methods based on the irreversible 9/7 tap filter. The section discussing rate control and JPEG codecs addresses bit allocation and packetization for rate control by *post compression rate distortion* (PCRD), which provides mechanisms for lossy compression methods based on the reversible 5/3 tap filter.

Distribution of Wavelet Coefficients

As an example, consider a video frame filtered by an analysis filter with low-pass coefficients $[-1/8, 2/8, 6/8, 2/8, -1/8]$ and high-pass coefficients $[1/2, 1, 1/2]$. This is a 5/3 tap filter because it has five low-pass and three high-pass filter coefficients. The low-pass coefficients provide a low-resolution version of the image, while the high-pass coefficients provide a low-resolution version of the residuals needed for perfect reconstruction of the image. Applying this filter (implemented in MATLAB) three times to a square window sized 240×240 pixels of *The Emotion of Space* in the RCT color space provides three levels of detail in both horizontal and vertical directions that yield the frequency distribution of wavelet coefficients shown in Figure 16.

The Laplacian distribution $y = \exp\left(-\left|\frac{x}{b}\right|\right)$ describes

the frequency distribution shown in Figure 16 for color components (V_1, V_2, V_3) where $a = (1.03, 1.19, 1.19) \cdot 10^8$, $(b = 6.96, 6.09, 6.02)$ with coefficient of determination

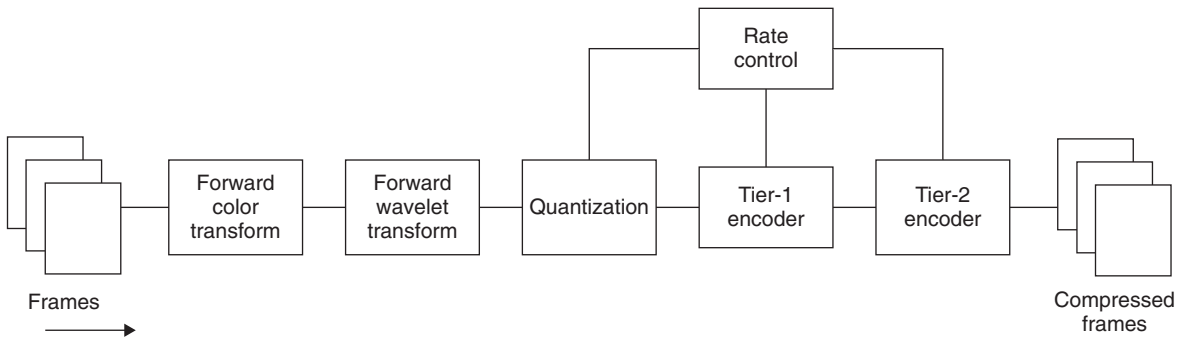

Figure 14: Block diagram for a Motion JPEG 2000 encoder

Figure 15: Block diagram for a Motion JPEG 2000 decoder

Figure 16: Frequency distribution of 5/3 tap wavelet coefficients after three-level analysis of *The Emotion of Space* in RCT color space

$r^2 = (0.849, 0.866, 0.867)$, respectively. The empirical distribution of wavelet transform coefficients is often Laplacian; the section on rate control and JPEG codecs will use this property to explain the derivation of a functional form for the rate-distortion function at low bit rates.

Temporal Domain

An alternative approach to video compression considers a sequence of images as multiple components of a single image, an approach supported by multiple component transforms defined in Part 2 of the JPEG 2000 standard. A two-dimensional spatial and one-dimensional temporal transform applied in any order provide a three-dimensional wavelet transform (e.g., Levy and Wilson 1999; Gokturk and Aaron 2006). If each single image comprises a group of frames, then the number of frames in the group is a key decision, based on considerations of error resilience and latency together with ease of editing, detecting scene changes, and detecting transitions.

In particular, U.S. Patent 6,823,129 to Goertzen discloses a motion image recording and storage system based on a three-dimensional transform, which Quvis developed into a practical digital cinema solution.

Three-Dimensional Compression

As a practical example, consider the compression of frames 1230 to 1679 of *The Emotion of Space* with the Kakadu implementation of the JPEG 2000 standard, choosing a 15-frame group of RGB frames for the multiple component transform. For this example, the encoder applies a YC_bC_r color transform to the color components of each frame to reduce spectral redundancy, a reversible 5/3-tap wavelet transform to both spatial components of each frame to reduce spatial redundancy, and a two-level Haar wavelet transform between adjacent frames to the luminance components Y to reduce temporal redundancy. The 5/3-tap wavelet transform has low-pass coefficients $(1, 0, 1.402, 1, -0.3441, -0.7141)$ and high-pass filter coefficients $(1, 1, .772, 0)$. The two-level Haar wavelet

Figure 17: Frame 1232 of *The Emotion of Space* after three-dimensional wavelet compression to 0.33 bpp per frame by the Kakadu implementation of a JPEG 2000 multiple component transform

transform yields the normalized sum and difference of luminance for corresponding pixels in adjacent frames and has matrix coefficients $\frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$. Figure 17 shows

frame 1232 of *The Emotion of Space* compressed to 0.33bpp target bit rate by this method. By visual inspection, the video quality is good with slight blurring and flickering. Strong visual edges appear to have occasional coronas. The measured average video quality metrics are PSNR = 35.72 and VQM = 4.14.

Psychovisual Domain

Video compression systems use perceptual methods for at least the following tasks: choosing color spaces, optimizing quantization matrices, assessing subjective quality, assessing practical significance of codec enhancements, suppressing flicker artifacts, and enhancing regions of interest.

Choosing Color Spaces

The earlier section on spectral domain indicated color spaces that reduce spectral redundancy based on the HVS being more sensitive to changes in brightness than color, with peak color sensitivity to green.

Optimization of JPEG Quantization Matrices

Regarding optimization of JPEG quantization matrices, U.S. Patent 5,629,780 to Watson discloses a method for image data compression having minimal perceptual error.

A series of psychovisual experiments measured the threshold luminance and chrominance at which observers could just notice individual DCT basis functions presented as images. The experiment varied viewing conditions, including the mean absolute luminance of the display device, the (veiling) luminance cast on the display device by background illumination, and the pixel size in terms of pixels per degree of visual angle (horizontal and vertical).

Consider the DCT coefficient of order (m, n) in image block with index k , denoted by $DCT(m, n, k)$, quantized to $QDCT(m, n, k)$ by a quantization matrix $Q(m, n, k)$, according to Equation 17:

$$QDCT(m, n, k) = \text{round} \left(\frac{DCT(m, n, k)}{Q(m, n, k)} \right) \quad (17)$$

Equation 17 indicates that the maximum possible quantization error is $Q(m, n, k)/2$.

Denote by $t(m, n, k)$ the observed threshold at which a typical viewer can just notice the DCT basis function of order (m, n) in image block with index k . Choosing $Q(m, n, k) < 2 \cdot t(m, n, k)$ ensures that typical viewers will not notice quantization errors.

Visual thresholds $t(m, n, k)$ increase with mean luminance of image block ("light adaptation") and decrease with the presence of patterns of similar spatial frequency and orientation ("contrast masking"). Furthermore, the perceived image quality depends on the perceptual quantization error from all image blocks, not only the block indexed by k .

Equation 18 gives an approximate power law formula for the effect of light adaptation on visual thresholds $t(m, n, k)$ for $m, n \neq 0$, valid for mean absolute luminance above 10 cd m^{-2} . Let $T(m, n)$ denote the visual thresholds determined in the above psychovisual experiments, with average DC coefficient set to $C(0, 0)$ when the display device has mean absolute luminance denoted by L_0 and (veiling) background absolute luminance denoted by $L_V = VL_0$:

$$t(m, n, k) = T(m, n, L_0) \cdot \left(\frac{V + DCT(0, 0, k)C(0, 0)}{V + 1} \right)^a \quad (18)$$

Typical values for the parameters in Equation 18 are $L_0 = 40 \text{ cd m}^{-2}$, $a = 0.65$, and $V = 0.05$. The average DC coefficient $C(0, 0)$ can usually be set to the nominal value 1024 for an 8-bit color component. Applying contrast masking to $t(m, n, k)$ threshold in accordance with the

widely used model developed by Legge and Foley (1980) results in the masked threshold $M(m, n, k)$ given by Equation 19 in terms of power law exponent $W(m, n)$ in the range $[0, 1]$:

$$M(m, n, k) = \max[t(m, n, k), DCT(m, n, k)^{W(m, n)} \cdot t(m, n, k)^{1-W(m, n)}] \quad (19)$$

For $W(m, n) = 1$, the threshold is proportional to the luminance, a behavior known as *Weber's law*. A typical empirical value for the exponent $W(m, n)$ is 0.7.

Expressing the quantization errors observed by a typical viewer as $d(m, n, k) \cdot M(m, n, k)$, the $d(m, n, k)$ values are measured in units of *just noticeable difference* (jnd). Equation 20 gives the perceptual error $P(m, n)$ for the DCT coefficients of order (m, n) obtained by pooling the quantization errors from all blocks using a widely used metric (the L_β norm). A typical value for $\beta(m, n)$ is 4:

$$P(m, n) = \left(\sum_k |d(m, n, k)|^{\beta(m, n)} \right)^{\frac{1}{\beta(m, n)}} \quad (20)$$

Finally, Equation 21 yields the overall perceptual error, P , obtained by pooling the $P(m, n)$ values with a possibly different exponent β_i :

$$P = \left(\sum_{m,n} P(m, n)^{\beta_i} \right)^{\beta_f} \quad (21)$$

If we choose the conservative value $\beta_f \rightarrow \infty$, then only the largest absolute error matters, and the perceptual error metric reduces to Equation 22:

$$P = \max(P(m, n)) \quad (22)$$

Minimizing the perceptual error, P , at specified bit rate R yields a quantization matrix optimized for each block k at bit rate R . The DCTune software tool currently available from the National Aeronautics and Space Administration (NASA) embodies these concepts.

Optimization of JPEG Quantization Matrices

As an example, consider using the DCTune software tool to compress frames 1230 to 1679 of *The Emotion of Space*, viewed from the default 7.125 picture heights, display device mean absolute luminance 40 cd m^{-2} , and default bit rate tolerance 5 percent.

With the goal of communicating *The Emotion of Space* over bidirectional videophones with acceptable video quality, Figure 18 shows a panel of gray-scale images representing color frame 1232 compressed by the DCTune software tool to target bit rates (a) 0.927, (b) 0.651, and (c) 0.33 bpp (corresponding to 384 kbps data rate).

The observed bit rates and corresponding PSNR and VQM video quality metrics for frames 1230 to 1679 are as follows:

- bit rate = $(0.9091 \pm 0.1139, 0.6405 \pm 0.0715, 0.3252 \pm 0.0217)$ bpp,

Figure 18: Panel of gray-scale images representing color frame 1232 of *The Emotion of Space* compressed by the DCTune coder to bit rates (a) 0.927, (b) 0.651, and (c) 0.33 bpp

8	8	8	10	16	40	255	255
6	10	8	10	14	24	255	255
8	8	14	28	255	255	255	255

255	255	255	255	255	255	255	255

Figure 19: Exemplary quantization matrix for luminance Y color component of frame 1232 of *The Emotion of Space* at 0.33 bpp target bit rate, compressed by the DCTune coder

- PSNR = $(40.53 \pm 3.32, 37.84 \pm 3.38, 10.7 \pm 0.39)$ dB, and
- VQM = (4.828, 4.632, 3.732), respectively.

At target bit rate 0.33 bpp, the video quality metric value VQM = 3.732 implies that, consistent with the results of visual inspection, DCTune compression provides video of acceptable quality because the impairments are perceptible but not annoying.

Figure 19 shows an exemplary quantization matrix for the luminance Y color component of frame 1232 at 0.33 bpp target bit rate.

Figure 20 is a gray-scale image that indicates the result of applying Equation 22 to pool overall perceptual errors over 16×16 -pixel regions for the same frame and bit rate, where lighter values indicate larger perceptual errors.

Practical Significance of Codec Enhancements

Although it is often useful to apply statistical tests to test the null hypothesis that the PSNR values resulting from codec comparisons have the same statistical distribution (statistical significance), it is even more useful to test whether the effect is large enough to be practically useful (practical significance). Many researchers consider a codec enhancement to be practically significant if it improves PSNR by 0.5 dB or VQM by approximately one unit on the DSIS scale.

Compare the video quality metric values VQM = (4.828, 4.632) at target bit rates (0.927, 0.651) bpp that result

Figure 20: Perceptual error map of frame 1232 of *The Emotion of Space* at 0.33 bpp target bit rate, pooled over 16×16 -pixel regions, compressed by the DCTune coder

from DCTune compression of frames 1230 to 1679 of *The Emotion of Space* with the values that result from Motion DCT compression of the same frames VQM = (3.191, 2.044) at the same bit rates (0.927, 0.651) reported in Figure 18. Because the VQM values improved by more than one unit on the DSIS scale, optimizing the quantization matrices has practical significance.

Suppressing Flicker Artifacts

To take account of the HVS's varying sensitivity to spatial frequencies, JPEG 2000 Part 1 Annex J.8 recommends weights for visual weighting schemes. These schemes include visual progressive coding, with layers separately weighted for the viewing conditions appropriate to each layer, by modifying the distortion weights for each component provided to the rate-distortion optimizer. JPEG 2000 Part 3 Annex B recommends weights for a five-level wavelet decomposition of YC_bC_r video, based on the observed typical visual CSF measured at the midpoint of each sub-band. Part 3, Annex B observes that visual weighting can reduce the incidence of some flickering artifacts that appear when displaying a visual sequence, even though individual images do not show an annoying artifact. Leontaris et al. (2006) suggest that many flickering artifacts are due to (1) small temporal variations in input luminance that give rise to large variations in dequantized wavelet coefficients and (2) uneven rate allocation between code blocks across subsequent frames. An intuitive approach is to truncate all code blocks to the same truncation length throughout each image or for as many images as possible.

Enhancing Regions of Interest

Part 1, Annex H of the JPEG 2000 standard supports region-of-interest signaling in which the encoder creates a mask selecting quantized transform coefficients for better quality encoding. A compliant encoder scales down the background (nonmasked) quantized transform coefficients with a scaling factor s chosen for each component so that the smallest nonzero foreground (masked) quantized transform coefficient is larger than the largest background coefficient. The encoder writes the scaling factor into the code stream. All coefficients less than 2^s belong to the background. A compliant decoder retrieves the scaling factor, s , for the current component from the code stream and scales up any coefficient less than $2^s \times 2^s$.

Foveated Regions of Interest

Faces and facial expressions often attract human attention. Rapid motion of peripheral objects across the field of view is often distracting (Colmenarez et al. 1999). Bounding regions of attention and distraction allow Motion JPEG 2000 to use the JPEG 2000 region-of-interest capability in Annex H to encode the regions at a relatively higher bit rate. Wang and Bovik (2001) incorporate HVS models into a scalable encoder. The HVS spatial resolution peaks in the direction the eye is currently looking (foveation point) and decreases dramatically away from this direction. Geisler and Perry (1998) report a CSF model that fits experimental data, given by Equation 23, where CT denotes the visible contrast threshold, CT_0 minimal visible contrast threshold, f spatial frequency (cycles/degree), e angular displacement of foveation point from observer's retina, α spatial frequency decay constant, and e_2 half-resolution angular displacement decay constant:

$$CT(f, e) = CT_0 \exp \left(af \frac{e + e_2}{e_2} \right) \quad (23)$$

Equation 24 gives their best-fit measurements:

$$\begin{aligned} a &= 0.106 \\ e_2 &= 2.3 \\ CT_0 &= \frac{1}{64} \end{aligned} \quad (24)$$

Equation 25 defines contrast sensitivity, CS , as the inverse of the contrast threshold:

$$CS(f, e) = \frac{1}{CT(f, e)} \quad (25)$$

Observing a point in an image of width N pixels, at distance d from the retina with perpendicular viewing distance v between the retina and the image plane measured in image widths, yields Equation 26 for the retinal angular displacement of a point in the image:

$$e = \tan^{-1} \left(\frac{d}{Nv} \right) \quad (26)$$

Equation 27 gives the highest perceptible frequency, f_m , which is the smaller of the Nyquist frequency, $f_{Nyquist}$, and the cutoff frequency at maximum contrast $CT_c = 1$:

$$\begin{aligned} f_{Nyquist}(v) &= \frac{1}{2} \frac{\pi N v}{180} \left(\frac{\text{cycles}}{\text{degree}} \right) \\ f_c(e) &= \frac{e_2 \ln \left(\frac{1}{CT_0} \right)}{\alpha(e + e_2)} \left(\frac{\text{cycles}}{\text{degree}} \right) \\ f_m(v, e) &= \min(f_{Nyquist}(v), f_c(e)) \end{aligned} \quad (27)$$

Hence, Equation 28 gives the foveation-based contrast sensitivity for viewing a point with spatial frequency f , at distance d from the retina, with perpendicular viewing distance v between the retina and the image plane:

$$S_f(v, f, d) = \begin{cases} \frac{CS(v, f, d)}{CS_0} & \text{if } f \leq f_m(v, d) \\ 0 & \text{otherwise} \end{cases} \quad (28)$$

The authors select human faces as foveation points in the wavelet transform domain, detected by a binary template-matching algorithm similar to that proposed by Wang and Chang (1996). The template includes bounds in chroma and bounding rectangle aspect ratio. Chroma bounds for skin tone are narrow for each race, regardless of ethnicity. Human faces are contiguous regions with typical aspect ratios in the range 1.4–1.6 and tilt $\pm 30^\circ$, so the typical aspect ratios of their bounding rectangles are in the range 1–1.7. The video frame size bounds the rectangles, together with a lower limit based on the threshold for face detection, typically 32×32 pixels. Noting that human faces have discontinuities at eyes, nose, and mouth, the algorithm accepts only candidate faces with sufficiently high pixel variance.

As a practical example, consider viewing an image from a typical distance of six image widths. Figure 21 shows the contrast sensitivity according to Equation 28 normalized to peak value 1.0. The *full width at half maximum*

Figure 21: Normalized contrast sensitivity versus displacement for viewing images 240 pixels wide from a perpendicular distance of six image widths

Figure 22: Foveated uncompressed image of *The Emotion of Space*, frame 1232, with fixation point within the rightmost astronaut's face

(FWHM) contrast sensitivity is approximately 60 pixels displacement centered on zero displacement.

Figure 22 displays a foveated image of *The Emotion of Space*, frame 1232, with fixation point within the rightmost astronaut's face.

The Kakadu implementation of the JPEG 2000 standard (Taubman and Marcellin 2001) supports regions of interest. Defining a mask with foreground regions of interest centered on each astronaut's face of width and height 60 pixels, covering approximately 14 percent of the pixels, allows encoding frame 1232 with twenty image layers at bit rates from lossless to 0.33 bpp rate, with distortion minimized at higher priority in the foreground than the background.

Rate Control

In general, the information content of digital video sources varies in complexity from scene to scene. *Constant bit rate* (CBR) encoding has the goal of maintaining a (near) constant bit rate for the transmission channel coder by varying the reconstructed video quality. *Variable bit rate* (VBR) has the goal of maintaining (near) constant quality by varying the bit rate allocated to scenes of varying complexity.

To achieve goals of CBR or VBR encoding, consider rate-control algorithms that control a generic block transform encoding process by encoding each image separately at a desired bit rate or image quality. In particular, they control the encoding process by adjusting the quantizer step size in accordance with the slope of the rate-distortion curve.

In particular, the Motion JPEG 2000 standard supports the *postdistortion rate control* algorithms recommended by Part 1, Annex J.10 of standard 15444-1 (ISO/IEC 2004a). These algorithms optimize the bit allocation by adjusting the quantizer step size according to the slope of the rate-distortion curve evaluated for each code block in each sub-band independently (see "Image Compression").

Generic Lagrangian Rate Control

To see how this works, consider an image decomposed into N sub-bands corresponding to the transform coefficients arranged into a linear sequence ($N = 64$ for the 8×8 -pixel DCT). In general, the transform coefficients have unequal variances, and the algorithm allocates bits to each sub-band to minimize the overall distortion. Normalizing the transform coefficient variance in sub-band i to unity by transform normalization factor T_i , a quantizer designed for transform coefficients with zero mean and unit variance can quantize the sub-band to bit rate R_i . Each sub-band contributes an amount $D_i(R_i)$ to distortion in the reconstructed image. If the distortion measure (such as mean square error) is additive across sub-bands, then the observed fraction of transform coefficients in sub-band i is n_i and the observed transform coefficient variance is σ_i , so the normalization factor is $T_i = \sigma_i^{-1}$. The resulting image distortion D is given by Equation 29, i th image bit rate R given by Equation 30:

$$D = \sum_{i=1}^N n_i T_i D_i(R_i) \quad (29)$$

$$R = \sum_{i=1}^N n_i R_i \quad (30)$$

In general, larger quantizer step sizes clear more coefficients (e.g., Equation 12). Adjusting the quantizer step size selects R_i by adjusting n_i and σ_i .

Minimizing the distortion, D , at a desired bit rate, $R < R_{\max}$, by the well-known method of Lagrange multipliers is equivalent to minimizing the functional L given by Equation 31:

$$L = \sum_{i=1}^N n_i T_i D_i(R_i) - \lambda \sum_{i=1}^N n_i R_i \quad (31)$$

Differentiating the functional L with respect to R_i yields Equation 32:

$$L' = \sum_{i=1}^N n_i [T_i D'_i(R_i) - \lambda] \quad (32)$$

Setting $L' = 0$ yields λ , given by Equation 33:

$$\lambda = T_i D'_i(R_i) \quad \forall i \in [1, N] \quad (33)$$

Hence, λ is proportional to the slope of the rate-distortion curve for sub-band i evaluated at bit rate R_i . The value of λ is the same for all sub-bands. In practice, the rate-control algorithm adjusts the quantizer step size for each sub-band i by a search method that solves the bit allocation Equation 33 using a theoretical or empirical form of rate-distortion function $D_i(R_i)$ and adjusting the value of λ until the algorithm achieves the desired overall bit rate R .

Figure 23: Uniform scalar quantizer with step size Δ

Rate-Distortion Function

To develop a theoretical rate-distortion function $D_i(R_i)$ for relatively high bit rates, consider the fixed-rate uniform scalar quantizer given by Equation 5 with step size $Q = \Delta$ depicted in Figure 23. This is termed a *midtread* quantizer because zero is a possible output value.

Assuming a uniform distribution of m -bit source data, Equation 34 gives the uniform scalar quantizer bit rate, R , and mean square error distortion, D (e.g., Sayood 2006):

$$R = m - \lfloor \log_2 \Delta \rfloor, \quad (34)$$

$$D = \frac{1}{12} \Delta^2 \Rightarrow D = \frac{1}{12} 2^{-2(R/m)} = \varepsilon^2 \bullet 2^{-2R}$$

Consider an image sampled from a source distribution with variance σ_x^2 . Equation 35 gives the mean square error distortion for image samples $D_x(R)$ quantized at rate R by a uniform scalar quantizer (or nonuniform scalar quantizer with sufficiently high resolution):

$$D_x(R) \cong \varepsilon^2 \sigma^2 x^{2^{-2R}} \quad (35)$$

Here ε^2 is a form factor depending on the source *probability distribution function* (pdf). The form factor for a uniform pdf is $\varepsilon^2 = \frac{1}{12}$.

Consider an orthonormal transform T with coefficients Y_n , $n = 0, \dots, N-1$ drawn from a distribution with variance $\sigma_{Y_n}^2$, each contributing R_n to the rate when quantized by a uniform scalar quantizer (or nonuniform scalar quantizer with sufficiently high resolution). Equation 36 gives the mean square error distortion for image samples at rate R resulting from quantization of transform coefficients to rates R_n , which is the rate-distortion function required by Equation 33:

$$R = \sum_{n=0}^{N-1} R_n \quad (36)$$

$$D_T(R) \cong \frac{1}{N} \sum_{n=0}^{N-1} \varepsilon^2 \sigma_{Y_n}^2 2^{-2R_n}$$

To obtain an empirical form for the overall rate-distortion function $D(R)$ useful for generic transforms and scalable video coders at low bit rates, Dai et al. (2004) combine the Laplacian empirical distribution of generic transform coefficients (e.g., the distribution of DCT and wavelet coefficients discussed above) with the almost linear empirical relation between the number of nonzero quantized generic transform coefficients and the observed bit rate (He and Mitra 2001). If the source variance is σ_x^2 , then Equation 37 expresses the resulting form of the overall rate-distortion function, $D(R)$, in terms of empirical coefficients a, b, c :

$$D = \sigma_x^2 - (a \log_2^2 R + b \log_2 R + c)R \quad (37)$$

Differentiating Equation 37 yields the slope of the rate-distortion curve $D'(R)$ required by Equation 33 for Lagrangian generic rate control.

Iterative Generic Rate-Control Algorithm

The Lagrangian generic rate-control algorithm explained above is accurate but computationally intensive, encoding every sub-band completely by entropy coding before adjusting the quantizer step size.

Tzannes (2002) describes a reasonably accurate but less computationally intensive iterative rate-control algorithm. Although initially intended for wavelet transforms, the algorithm is applicable to arbitrary sub-band transforms and proceeds by:

1. compressing the first image of the sequence to a bit rate $R_{achieved}$ based on an empirical value of λ determined by rate-distortion analysis;
2. repeating steps 3 to 5 until the algorithm has compressed the last image of the sequence;
3. calculating the rate-control error between the achieved bit rate $R_{achieved}$ and target bit rate R_{target} as

$$RC_{error} = \frac{R_{achieved} - R_{target}}{R_{target}} \quad (38);$$

4. correcting the value of λ using first-order control,

$$\lambda_{new} = \lambda_{previous} * (1 - RC_{error}) \quad (39); \text{ and}$$

5. compressing the next image in the sequence based on λ_{new} .

Iterative Rate Control

Consider applying the iterative rate-control algorithm expressed by steps 1 to 5 above to frames 1230 to 1679 of *The Emotion of Space* with Motion JPEG 2000 compression and target bit rate 0.33 bpb. Figure 24 shows the result of compressing frame 1230 to a range of bit rates from 0.1 to 1.0 bpb by the Kakadu implementation of JPEG 2000 with a single-layer reversible transform (Taubman and Marcellin 2001).

Denoting by D the mean square error distortion and by R the bit rate, the Equation $\log_{10}(D) = D_0 + a \log_{10}(R)$

Figure 24: Mean square error versus bit rate (bpp) for *The Emotion of Space*, frame 1230, encoded by the Kakadu implementation of the JPEG 2000 reversible transform

fits the curve shown in Figure 24 with $D_0 = 0.8826$, $a = -1.322$, and coefficient of determination $r^2 = 0.9909$. The interpolated rate-distortion slope $\lambda = -43.66$ at target bit rate 0.33 bpp. Applying the iterative rate-control algorithm, defined by steps 1 to 5 above, to frames 1230 to 1679 of *The Emotion of Space* yields bit rates with coefficient of variation 0.98 percent, compared to the more accurate but computationally intensive Lagrangian rate-control algorithm, which yields bit rates with coefficient of variation 0.75 percent.

Error Resilience

Transmission channels are often prone to error (see “Sources of Errors, Prevention, Detection, and Correction”). Because the JPEG standards encode frames independently, the damaging effect of channel errors does not propagate across frames. In particular, Motion JPEG 2000 further relies on resynchronization markers and data partitions for limiting error propagation such as code blocks (spatial domain) and precincts (wavelet domain). The resynchronization markers are special codes inserted by encoders that enable decoders to resynchronize in the presence of errors. The current JPEG 2000 standard does not recommend any specific error correction or concealment method. (For a review of video error concealment methods, see Wang and Zhu 1998.)

Dufaux and Ebrahimi (2003) simulation experiments indicate that Motion JPEG 2000 is highly resilient to channel errors that are typical of low bit rate wireless channels.

Scalability

In streaming video applications, the servers often serve a large number of users with differing screen resolutions and network bandwidth. In particular, the available Internet network bandwidth fluctuates over a wide range because of factors such as traffic variability and network congestion. Spatially scalable coding provides different resolutions, while temporally scalable coding provides

different temporal resolutions (or frame rates) to accommodate different users by widening the range of bit rates. *Signal-to-noise ratio* (SNR) scalable coding ensures a minimum video quality at the receiver end by sacrificing the least important information when transmission errors and packet losses occur. Encoders may truncate embedded bit streams provided by fine granularity scalable coding to arbitrary quality, spatial, or temporal resolution.

In the progressive DCT-based mode, a Motion JPEG encoder codes 8×8 -pixel blocks in zigzag order in multiple scans through each image. At each scan, the encoder either partially codes the DCT coefficients for each block by selecting bands of coefficients for coding each block (spectral selection), selecting ranges of bits for coding each coefficient with the most significant bits encoded first (successive approximation), or both. In the hierarchical mode, a Motion JPEG encoder may encode each image as a succession of frames. The first frame for each component provides a reconstructed reference frame for prediction in subsequent frames that encodes the differences between source components and reference reconstructed components. A Motion JPEG encoder in hierarchical mode may build a pyramid of spatial resolutions by up- or downsampling the source components. A Motion JPEG encoder may offer the capability of progressive coding to a final lossless stage if the encoder codes the differences by lossless methods at the final stage.

In the near-lossless mode, a Motion JPEG-LS encoder may adjust the quantization of prediction residuals to control the maximum absolute error between a reconstructed image component and the corresponding value in the original image.

The JPEG 2000 standard recommends SNR and fine granularity scalable coding for each image via multiple layers of *embedded block coding with optimized truncation* (EBCOT) (see “Data Compression”). Motion JPEG 2000 encoders may provide SNR and fine granularity spatially scalable coding of image sequences by derivation from the JPEG 2000 standard.

Applications

This section explores practical applications of the concepts discussed previously.

Digital Cinema System

As an example of Motion JPEG 2000 compression, the Digital Cinema Initiatives (DCI) consortium's Digital Cinema System Specification v. 1.0 specifies that digital cinema decoders must support Motion JPEG 2000 compression for each video frame (Digital Cinema Initiatives 2005). Two formats are specified: (1) a 4K format comprising 4096×2160 pixel frame size, 36-bpp color depth, and 24 fps frame rate; and (2) a 2K format specified at a 2048×1028 pixel frame size, 36-bpp color depth, and a choice of either 24 or 48 fps frame rate.

To reduce spectral redundancy, the DCI consortium specified a color space defined in terms of CIE primary colors $X'Y'Z'$, displayed as output values XYZ by a display device with nonlinear response. Equation 40 specifies the overall color space with luminance and chrominance measured in absolute values (cd/m^2):

$$X = P \times \left(\frac{X'}{4095} \right)^{2.6}, Y = P \times \left(\frac{Y'}{4095} \right)^{2.6}, Z = P \times \left(\frac{Z'}{4095} \right)^{2.6}$$

$$X' \in [0 \dots 4095], Y' \in [0 \dots 4095], Z' \in [0 \dots 4095]$$

$$P = 53.27 \text{ cd/m}^2$$
(40)

Notable digital cinema releases include *Chicken Little* (Disney) and *Moonmathora!* (Mayalolam).

Mars Exploration Rover Camera System

NASA's Mars Exploration Rover (MER) mission currently carries nine cameras for navigation and reconnaissance. According to Kiely and Klimesh (2003), the MER onboard system uses ICER, an algorithm closely related to JPEG 2000, to compress each 1024×1024 -pixel image independently at 12-bit depth to bit rate from approximately 1 bit/pixel to nearly lossless. The MER transmission channel has fixed length packets. To fill the transmission packets efficiently, ICER implements a rigorous byte quota, together with a quality goal, whichever comes first. To contain transmission channel errors, ICER partitions the wavelet coefficients into precincts corresponding to rectangular regions in each image. The MER onboard system transmits each precinct separately.

ITU CODECS

The International Telecommunication Union (ITU) recommends a series of standards for the moving picture component of audiovisual services.

ITU-T Standards H.261, H.262, H.263, and H.264

H.261

ITU standard H.261 recommends a video codec for audiovisual services over telephone lines at $p \times 64$ kbit/sec where p is in the range of 1 to 30. Intended for use at video

bit rates between 40 kbit/sec and 200 kbit/sec, the codec was standardized initially in 1990 and revised in 1993. The source coder operates on noninterlaced pictures occurring at 30,000/1001 fps (approximately 29.97 fps) in either *common intermediate format* (CIF) or quarter CIF (QCIF) with frame sizes 352×288 and 176×144 pixels, respectively. Videoconferencing over telephone lines is an appropriate application for the H.261 standard, which is a superseded standard maintained for backward capability.

H.262

The ITU and the Motion Picture Experts Group (MPEG) jointly standardized H.262, also known as MPEG-2. This chapter discusses the popular MPEG-2 codec below under "MPEG Codecs."

H.263

ITU standard H.263 addresses video coding for low bit rate video communications for arbitrary video bit rate, standardized initially in 1997 and revised in 2005. The source coder can operate on five standardized video source formats that are submultiples or multiples of CIF: sub-QCIF, QCIF, CIF, 4CIF, and 16CIF. The coder can operate using a broad range of custom video formats. Profiles are subsets of the standard that are intended for a specific range of applications. Videoconferencing is an appropriate application for the H.263 standard.

H.263 is a superseded standard, also maintained for backward capability.

H.264

The ITU and MPEG jointly standardized H.264, also known as MPEG-4 Part 10 or *advanced video codec* (AVC). This standard recommends coding methods for the moving picture component of audiovisual services with the intention of providing twice as much compression as previously standardized codecs without using a substantially increased computational resource. The source coder can operate on noninterlaced and interlaced video components. Applications cover, among other things, digital storage media, television broadcasting, and real-time communications including videoconferencing. Profiles are subsets of the standard that are intended for a specific range of applications. In many applications, it is currently neither practical nor economic to implement a decoder that is capable of dealing with all of the hypothetical uses of a particular profile, so the standard further specifies levels within each profile. This chapter discusses the H.264 profiles below. H.264 is the most efficient, compressive, and flexible ITU codec to date, so it forms the primary topic of this section.

Generic Encoder and Decoder

Each ITU standard includes the specification of a *hypothetical reference decoder* (HRD). An encoder complies with a standard if it encodes a bit stream decodable by the HRD.

Figure 25 illustrates a block diagram for a generic ITU decoder, which is considerably simpler than that for the generic encoder.

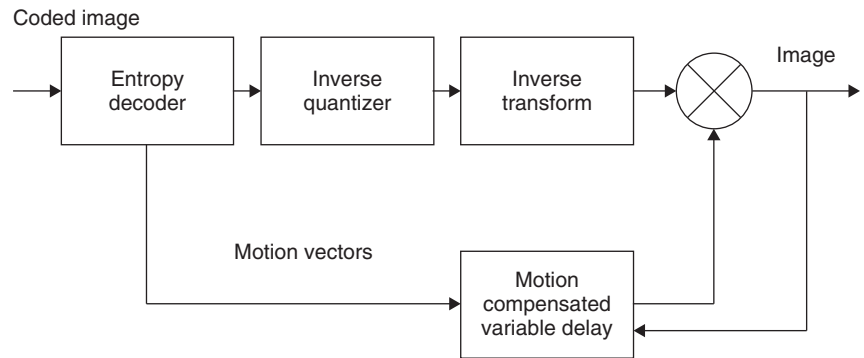

Figure 25: Block diagram for a generic ITU decoder

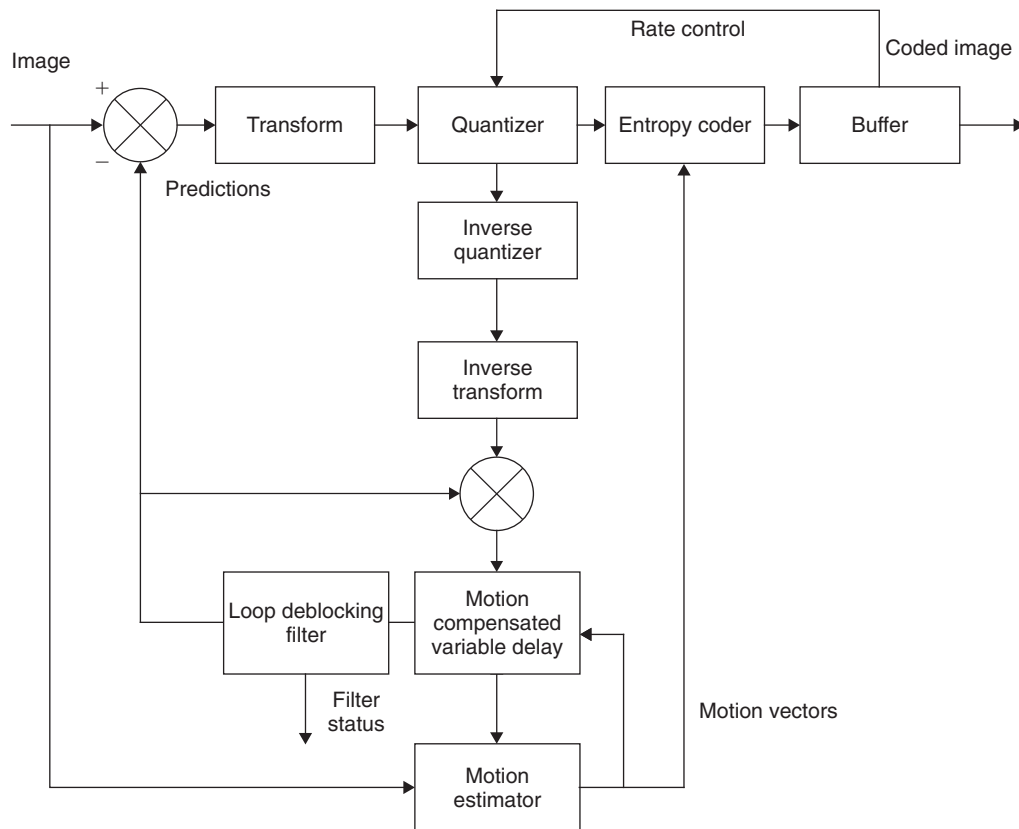

Figure 26: Block diagram for a generic ITU source encoder

Figure 26 shows a block diagram for a generic ITU source encoder. The source encoder reduces spatial, spectral, temporal, and psychovisual redundancy by prediction, block transformation, and quantization.

Spatial Domain

H.261

The H.261 standard specifies encoding and decoding of picture sequences. Each of the CIF and QCIF noninterlaced picture formats comprises luminance and color difference samples, with the color difference samples at half the resolution of the luminance samples. In accordance with ITU Recommendation BT.601 (the current version in force is BT.601-7), H.261 encodes luminance samples in the range 16 (black) to 235 (white) and color difference

samples in the range from 16 to 240, with the zero level of color difference encoded as 128. H.261 partitions each picture into *groups of blocks* (GOBs), macroblocks, and blocks. A GOB is a region defined by 176×48 pixels of luminance samples and the spatially corresponding 88×24 pixels of color difference samples for each color component. A macroblock is 16×16 pixels of luminance samples and the spatially corresponding 8×8 pixels of color difference samples for each color component. A block is 8×8 pixels of luminance samples and the spatially corresponding 4×4 pixels of color difference samples for each color component. In the decoder, H.261 recommends a deblocking filter to reduce the incidence of visible blocking artifacts. An H.261-compliant encoder codes pictures independently (*intra* mode) or by reference to past pictures decoded and stored in a buffer (*inter* mode).

The H.261 standard recommends transforming picture samples by an 8×8 DCT. The standard further recommends quantizing AC coefficients with the scalar quantizer defined in Equations 12 and 13 above, using the same quantization parameter $Q \in [2, 4, 6 \dots 60, 62]$ for all coefficients in a macroblock. H.261 recommends quantizing DC coefficients with fixed step size $Q = 8$ and further recommends arranging the coefficients in zigzag order, encoding zero-quantized transform coefficients by run-length encoding, with separate encoding for blocks in which all quantized transform coefficients are zero. H.261 also recommends encoding the resulting bit stream with an entropy coder in the form of a specific variable length code. In the decoder, H.263 recommends a deblocking filter to reduce the incidence of visible blocking artifacts.

H.263

The H.263 standard specifies decoding of picture sequences. The H.263 specification partitions each picture into GOBs or slices. A GOB comprises $k * 16$ lines, where k is an integer in the range 1 to 4, depending on picture format and encoder resolution mode. H.261 further partitions each GOB into macroblocks. Each macroblock is 16×16 pixels of luminance samples and the spatially corresponding 8×8 pixels of color difference samples for each color component, except in *reduced resolution update* (RRU) mode. In the RRU mode, each macroblock is 32×32 pixels of luminance samples and the spatially corresponding 16×16 pixels of color difference samples for each color component. A block is 8×8 pixels of luminance samples and the spatially corresponding 4×4 pixels of color difference samples for each color component. The criteria for choice of mode and transmitting a block are not subject to recommendation. Slices are rectangular picture regions comprising a whole number of macroblocks, and the H.263 standard allows transmission of the corresponding transform coefficients in arbitrary macroblock order. H.263 recommends transforming transmitted blocks using an 8×8 DCT, quantizing and entropy coding the resulting coefficients with a variable length code. The standard defines a quantization process similar to that defined for the H.261 standard, except that H.263 does not define the quantizer decision levels. An H.263-compliant encoder codes pictures independently (intra mode) or by reference to immediate past or future pictures decoded and stored in a buffer (inter mode).

H.264

The H.264 standard enables encoding and decoding of image sequences. An encoder can choose whether to scan any of the images in a progressive or field-interlaced manner (see "High Definition Television (HDTV)"). The H.264 standard also supports high-definition television standards through scalable aspect ratio, resolution, and frame rate.

Images intended for interpretation by an H.264 decoding process are termed *primary pictures*. Each primary picture can be associated with at least one *auxiliary picture* comprising information (such as opacity samples) intended for interpretation by a display process. A cropping rectangle specifies the width and height of primary pictures.

An H.264 compliant encoder codes images independently (intra mode) or by reference to arbitrary past or future images decoded and stored in a buffer (inter mode).

H.264 supports *intra* (I), *predicted* (P), and *bidirectionally* (B) predicted pictures, with exemplary temporal structure of I, P, and B pictures shown in Figure 27.

Each image comprises one or more sample arrays, representing monochrome (luma) or color (chroma) samples with or without auxiliary arrays. The terms *luma* and *chroma* avoid implying a linear transfer function that is often associated with absolute luminance and chrominance.

Each image comprises an integer number of *macroblocks*, each comprising 16×16 luma samples and any chroma samples associated with the luma samples. *Slices* partition images into arrays of macroblocks. Figure 28 illustrates a picture divided into two slices. The H.264 standard further characterizes slices as *intra* (I), *predicted* (P),

Figure 27: Example of temporal picture structure. Reproduced by permission of ISO

Figure 28: A picture divided into two macroblock slices after H.264. Reproduced with the kind permission of ITU

bidirectionally (B) predicted, *switching intra* (SI), and *switching predictive* (SP). The SP slice type facilitates efficient switching between precoded pictures, especially between pictures from bit streams coded at different rates, while the SI slice type facilitates random access and error recovery. *Macroblock to slice group maps* further group slices into sets of macroblocks, which is useful for defining foreground, background, and special patterns such as checkerboards and regions of interest. *Submacroblocks* partition each macroblock in regions as small as 4×4 luma samples. Figures 29, 30a, and 30b illustrate the Morton scanning order for macroblocks and submacroblock partitions, starting from the upper-left sample.

When coding in intra mode, an encoder begins by predicting the current macroblock or submacroblock luma and chroma from a context formed from its available decoded neighbors. The H.264 standard specifies three categories of intra mode spatial prediction: *intra* 16×6 , *intra* 8×8 , and *intra* 4×4 . In the intra 16×16 mode, an encoder predicts the luma component of all 16×16 pixels of a macroblock from samples of its available decoded and reconstructed (but not filtered) macroblock neighbors. An encoder can choose between predictions made in four modes: vertical, horizontal, DC, and plane.

H.264 Prediction of Intra-Coded Luma Samples

Figure 31 shows a luma (Y) macroblock that contains an astronaut's face from frame 1232 of *The Emotion of Space* and has been transformed from RGB to $YCbCr$ color space. This macroblock is bounded by frame coordinates (112, 80) to (127, 95) in the 240×320 -pixel frame. In Figure 31, this macroblock is bounded by image coordinates (2, 2) to (17, 17) as measured from the top lefthand corner. Figure 31 additionally depicts an image row from the macroblock above the current macroblock and an image column from the macroblock to the left of the current macroblock.

Figure 32 shows the intra 16×16 luma predictions for the macroblock in Figure 31, together with a quality metric, the median absolute error (MAE). The vertical

Figure 32: Intra 16 × 16 luma predictions for the macroblock shown in Figure 31, together with their MAE. The horizontal prediction has the least MAE

mode copies the top row of available previously decoded pixels (H) into all rows of the predicted macroblock. The horizontal mode copies the left column of available previously decoded pixels (V) into all columns of the predicted macroblock. The DC prediction averages the H and V pixels uniformly across the predicted macroblock, adding 0.5 to the predicted luma value before rounding. The plane prediction applies bilinear interpolation to the H and V pixels of the predicted macroblock, adding 0.5 to the luma value before rounding and clipping m -bit luma values to the range $[0, 2^m - 1]$. In this example, the horizontal prediction has the least MAE of these four prediction modes. Although an H.264-compliant encoder may reasonably select the intra 16 × 16 horizontal luma prediction mode, the standard does not oblige it to do so.

The H.264 standard specifies nine directional prediction modes for 8 × 8 luma and 4 × 4 luma submacroblocks. These prediction modes result from bilinear interpolation of the available previously decoded samples above and to the left of the current submacroblock, with coefficients specified for each direction. If the macroblock luma samples are predicted by intra coding, then so are the associated chroma samples with 8 × 8 prediction modes similar to those described above for 16 × 16 luma samples. “Temporal Domain” below addresses methods for reducing temporal redundancy together with inter-coding modes.

The decoder needs to know the prediction modes for each 4 × 4 submacroblock. Because prediction modes between adjacent submacroblocks within the same slice are typically highly correlated, the decoder calculates and applies the most probable mode unless it receives side information in the form of an eight-valued mode selector.

The encoder transforms each macroblock or submacroblock partition of residuals after the prediction modes are decided and the predictions have been subtracted from the corresponding pixel values. A hierarchical encoder can dynamically select any of the partition sizes indicated in Figure 29 for its tree structure. Selecting small partition sizes near edges and larger partition sizes in smooth regions tends to reduce blocking artifacts.

One approach to H.264 mode selection is to perform a full search of prediction mode space to select the prediction mode that minimizes a measure of distortion according to a Lagrangian functional. Jagmohan and Ratakonda (2004) report a relatively time-efficient learning algorithm for H.264 mode selection that uses a simple distortion measure and fast search for motion vectors.

Spatial Transform

The H.264 standard transform for 4 × 4 submacroblocks is a low-complexity *integer cosine transform* (ICT), an integer approximation to the DCT defined by Equation 41:

$$\text{Define } a = \frac{1}{2}, b = \sqrt{\frac{1}{2}} \cos\left(\frac{\pi}{8}\right), c = \sqrt{\frac{1}{2}} \cos\left(\frac{3\pi}{8}\right).$$

$$DCT_{4 \times 4} = \begin{bmatrix} a & a & a & a \\ b & c & -c & -b \\ a & -a & -a & a \\ c & -b & b & -c \end{bmatrix}$$

$$ICT_{4 \times 4} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 2 & 1 & -1 & -2 \\ 1 & -1 & -1 & 1 \\ 1 & -2 & 2 & -1 \end{bmatrix} \quad (41)$$

ICT calculations are reversible in integer arithmetic and require only additions and shifts. The ICT is real and orthogonal but not orthonormal. The ICT has the same matrix structure as the 4×4 DCT.

Similarly, the H.264 standard defines an 8×8 ICT for 8×8 submacroblocks. When the encoder selects the 16×16 intra prediction mode with the 4×4 transform, the 16 DC coefficients of the 4×4 luma submacroblocks are selected and further transformed by a 4×4 Hadamard transform for increased compression in visually smooth regions as are the DC coefficients of all 4×4 chroma submacroblocks. Equation 42 gives the 4×4 Hadamard transform:

$$H_{4 \times 4} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \\ 1 & -1 & 1 & -1 \end{bmatrix} \quad (42)$$

The Hadamard transform is real, symmetric and orthogonal, and reversible in integer arithmetic, and it requires only additions and subtractions.

Quantizer

A uniform scalar dead zone quantizer quantizes the transformed picture components. Referring to Figure 23, which depicts a one-sided uniform scalar quantizer, a uniform scalar dead zone quantizer additionally quantizes to zero all coefficients having absolute value less than a predetermined threshold. This ensures that a zero reconstruction level is available (see Yu 2004). The H.264 standard specifies a scalar quantizer according to a choice of fifty-two step sizes indexed by a *quantization parameter* (QP). An increase of approximately six in QP doubles the quantizer step size. An encoder can choose different values of QP for luma and chroma components. Note that the quantizer incorporates scaling factors for the ICT, an orthogonal but not orthonormal transform.

Reminiscent of the JPEG standards, a *zigzag scan* (frame mode) or *alternate scan* (field mode) orders the quantized transform coefficients corresponding to each 4×4 submacroblock so that higher-variance coefficients are traversed earlier and the run lengths of zero are increased.

Entropy Coder

H.264 standardizes a choice of entropy coders to encode the scan, including *context adaptive variable length code* (CAVLC) and *context adaptive binary arithmetic coding* (CABAC). For CAVLC, the H.264 standard provides a syntax element to report the total number of nonzero-quantized transform coefficients in a scan, together with the number of trailing ones, defined as consecutive transform coefficient levels equal to 1 at the end of a scan. Note that He and Mitra (2001) found an almost linear relationship between the number of nonzero coefficients and rate for several algorithms closely related to H.264, including H.263 and MPEG-4. The term *context adaptive* means that an encoder implementing CAVLC can choose between several VLC tables according to the local statistics of the bit stream. CABAC maintains separate arithmetically encoded streams for different H.264 syntax elements and

typically provides increased coding efficiency relative to CAVLC, with considerably increased demands on computational resources. Transform coefficients account for the vast majority of syntax elements coded by CABAC. Osorio and Bruguera (2006) point out that even though CABAC provides a 10 percent to 15 percent improvement over baseline CAVLC entropy coding, the real-time H.264 encoding of standard and high-definition television video sequences requires at least millions of symbols per second when the encoder uses CABAC rather than CAVLC. The processor workload increases by approximately two orders of magnitude if the encoder also uses *rate-distortion optimization* (RDO), which is a method of trying several different encoding modes to find one that optimizes the balance between bit rate and distortion.

Marpe et al. (2003) provide a rationale for CABAC from the viewpoint of an encoder. The encoding process includes the steps of *binarization*, *context modeling*, and *binary arithmetic coding*. Binarization maps a binary sequence, termed a *bin string*, to a specified syntax element. Each binary element of a bin string is termed a *bin*. If the syntax element is binary-valued, then binarization is equivalent to a step of identity mapping. In the regular coding mode, context modeling includes selecting a probability model that may depend on previously coded syntax elements or bins, followed by selecting a regular arithmetic coding engine. In the bypass coding mode, context modeling includes selecting a simplified arithmetic coding engine without selecting an explicit context model. Arithmetic coding includes encoding the bin with a binary arithmetic coder.

Loop Deblocking Filter

The H.264 standard recommends an optional in-loop deblocking filter to reduce the visual annoyance from blocking artifacts resulting from ringing at 4×4 -pixel or 8×8 -pixel block boundaries. The filter provides a modest improvement of approximately 0.3 dB PSNR (Wei et al. 2005) at considerable implementation cost. Zhong et al. (2005) demonstrate that human viewers do not always prefer this adaptive filter and that subjective tests indicate a bimodal distribution of preferred filter strengths.

Spectral Domain

H.261 and H.263

The H.261 and H.263 standards support monochrome and $YCbCr$, color spaces with 4:2:0 color-sampling schemes (see "High Definition Television (HDTV)"), with color-difference samples located between the corresponding luminance samples.

H.264

Standard H.264 supports 4:2:0, 4:2:2, and 4:4:4 color-sampling schemes and directly supports monochrome, RGB, and $YCbCr$, color spaces, together with unspecified monochrome or CIE color tri-stimulus values, usually denoted by XYZ, with or without an auxiliary array for quantities such as opacity. Recently, Malvar and Sullivan (2003) proposed a reversible color transform of residuals from RGB (4:4:4) to a $YCbCr_g$ color space with color differences relative to orange and green, respectively. Equations

43 and 44 respectively define the direct and inverse RCT color transforms:

$$\begin{bmatrix} Y \\ C_o \\ C_g \end{bmatrix} = \begin{bmatrix} \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \\ \frac{1}{4} & 0 & \frac{1}{4} \\ \frac{2}{4} & \frac{1}{2} & \frac{2}{4} \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (43)$$

$$\begin{bmatrix} R \\ G \\ B \end{bmatrix} = \begin{bmatrix} 1 & 1 & -1 \\ 1 & 0 & 1 \\ 1 & -1 & -1 \end{bmatrix} \begin{bmatrix} Y \\ C_o \\ C_g \end{bmatrix} \quad (44)$$

A reversible integer color transform results from applying an S transform (Adams et al. 2002) to the direct color transform defined by Equations 43 and 44. By definition, a forward S transform maps the integer vector $\begin{bmatrix} x_0 \\ x_1 \end{bmatrix}$ to the integer vector $\begin{bmatrix} y_0 \\ y_1 \end{bmatrix}$ by the transformation Equation 45, with corresponding inverse S transform defined by Equation 46:

$$\begin{bmatrix} y_0 \\ y_1 \end{bmatrix} = \begin{bmatrix} \frac{1}{2}(x_0 + x_1) \\ x_0 - x_1 \end{bmatrix} \quad (45)$$

$$\begin{bmatrix} x_0 \\ x_1 \end{bmatrix} = \begin{bmatrix} t \\ t - y_1 \end{bmatrix}, t \gg y_0 + \left\lfloor \frac{1}{2}y_0 + 1 \right\rfloor \quad (46)$$

Applying Equation 45 to Equation 43, Equation 47 yields the forward integer RCT, where \gg denotes the arithmetic shift operator. Equation 48 yields the inverse integer RCT corresponding to Equation 44:

$$\begin{aligned} C_o &= R - B \\ temp &= B + (C_o \gg 1) \\ C_g &= G - temp \\ Y &= temp + (C_g \gg 1) \end{aligned} \quad (47)$$

$$\begin{aligned} temp &= Y - (C_g \gg 1) \\ G &= C_g + temp \\ B &= temp - (C_o \gg 1) \\ R &= B + C_o \end{aligned} \quad (48)$$

Malvar and Sullivan (2003) report that this reversible color transform yields a coding gain of 4.54 dB on the widely used 24-image RGB Kodak color still image set available from the Rensselaer Polytechnic Institute Center for Image Processing Research.

Temporal Domain

H.261

Recall that Motion JPEG 2000 compresses each picture independently. The H.261 standard allows an encoder to

choose whether to encode each picture independently (intra coding) or relative to predictions based on previously reconstructed pictures (inter coding). The H.261 standard recommends forcing the encoder to intra mode with an update pattern that the encoder is free to choose. The suggested pattern is to update at least once every 132 transmitted pictures to control the accumulation of irreversible DCT mismatch errors. Although the encoder is free to choose the method of interpicture prediction, the H.261 standard specifies optional motion compensation (see Jain 1989 or Sayood 2006), followed by an optional spatial loop deblocking filter to reduce the incidence of blocking artifacts.

The H.261 standard specifies motion compensation between pictures in terms of motion vectors encoding differences between pictures. The decoder will accept one motion vector per macroblock for the luminance component to pixel accuracy. The standard specifies halving this motion vector and rounding the values toward zero to obtain a motion vector for both color components. Moving cameras (pan and zoom), moving objects, shadowing, changing lighting, and editing video all contribute to differences between pictures.

Accordingly, the H.261 standard specifies that horizontal and vertical motion vector components must be in the range $[-15 \dots 15]$ pixels and that valid motion vectors must be within the coded picture area. A positive value for the horizontal or vertical motion vector component indicates that the corresponding macroblock is spatially to the right or below the predicted macroblock. The encoder is free to choose the method for determining motion vectors.

H.263

The H.263 standard allows an encoder to choose whether to encode each picture by intra coding or relative to predictions based on a previous intrapicture (P pictures) or one previous and one future intrapicture that have the same picture size (B pictures). There are four optional additional types of predicted picture: PB, improved PB, EI, and EP.

The decoder accepts one motion vector per macroblock to half-pixel accuracy unless the decoder selects the optional *advanced prediction mode*, when the decoder accepts four motion vectors per macroblock to half-pixel accuracy. In the optional *unconstrained motion vectors* mode, motion vectors may point outside picture boundaries.

H.264

The H.264 standard allows an encoder to choose whether to encode each picture or each slice by intra coding or relative to predictions based on arbitrary previous and future pictures, including predicted pictures (inter coding). The H.264 standard supports variable block sizes for motion compensation, from the 16×16 macroblock to the 4×4 submacroblock, and accepts as many as 16 motion vectors per macroblock stored at quarter-pixel precision. The motion vectors may point outside the picture boundaries. Choi and Jeon (2006) describe a hierarchical motion search for H.264 variable-block-size motion compensation that provides quality (PSNR) similar to full search

but approximately 10 times faster by adjusting the search center and search pattern according to the distribution of sub-block motion vectors.

H.264 Interframe Motion Compensation

Interframe coding is a method of reducing redundancies between successive images. It is especially useful when there is little change in content from one image to the next.

Motion compensation seeks to encode differences between frames, considering moderate motion. Moving visual objects, moving cameras, changing lighting conditions, and editing scenes all contribute to differences between successive images in a video sequence.

To see how this works, consider a buffer storing a number N of available decoded frames (typically five). The frames can be past, present, or future. To simplify this discussion, choose $N = 2$ and focus on a specific block B_1 in image I_1 . If an encoder can find a closely matching block B_2 in image I_2 , then the vector location of block B_2 in image I_2 relative to the location of block B_1 in image I_1 is termed the *motion vector*. The H.264 standard recommends differential encoding of motion vectors for transmission.

Consider again frames 1231 to 1233 of *The Emotion of Space* and, in particular, the astronaut's face macroblock in frame 1232, bounded by frame coordinates (112, 80) to (127, 95). Frame 1232 is a scene change from frame 1231; as the astronaut walks forward from frame 1232 (time code 01:22.133) to frame 1233 (time code 01:22.200), audience flash photography enhances luma and blue chroma. By visual inspection, the astronaut's face is not present in frame 1231.

To obtain motion vectors to half-pixel and quarter-pixel accuracy, a compliant encoder first interpolates luma samples to half-pixel precision by filtering horizontally, vertically, or both with the six-tap *finite impulse response* filter $\frac{1}{32} \begin{bmatrix} 1 & -5 & 20 & 20 & -5 & 1 \end{bmatrix}$. Averaging

neighboring values horizontally, vertically, or diagonally yields quarter-pixel interpolation. Likewise, a compliant encoder interpolates chroma samples by bilinear interpolation to quarter-pixel or eighth-pixel accuracy as required.

An encoder is free to choose the method for matching blocks. Typically, an encoder selects a matching block by minimizing an error metric such as the MSE or MAE. If the error metric exceeds a specific threshold or a spatial prediction is a closer match, then an encoder may decide to intra code the block. One possible method for matching blocks is a full search, which is resource intensive but easy to parallelize. Alternatives to full search include *logarithmic search*, *hierarchical search*, *conjugate direction*, and *gradient search* techniques (Jain 1989).

As an example, Figure 33 illustrates the popular three-step search (TSS) introduced by Koga et al. (1981). Starting with a predicted search center, the encoder searches a 6×6 -pixel region around the search center with 3-pixel step size, evaluating an error metric at the search center's eight nearest neighbors. The position yielding the minimum error becomes the new search center (shaded in

Figure 33: Three-step search converging on a position of minimum error at (2, -1)

Figure 34). The encoder repeats the search from this new center, decrementing the step size by one, until it finds the best match or decides to intra code the block.

Let us apply TSS on a pixel grid to match the luma macroblock bounded by frame coordinates (112, 80) to (127, 95) in frame 1232 with a luma macroblock in frame 1233, based on initial search center (120, 88) in frame 1233 coordinates. If we use the MAE, the result is motion vector (+2, +3) with MAE = 4. Let us further refine the search of nearest neighbors on a half-pixel grid starting from the match found on the pixel grid, followed by a refinement search of nearest neighbors on a quarter-pixel grid starting from the match found on the half-pixel grid. The result is the motion vector (+2.0, +3.0) to quarter-pixel accuracy. Because the best match intra prediction results in a value of MAE = 8.85, an encoder may choose inter prediction based on the frame 1233 interpolated macroblock values found in the search. If an encoder decides to use more than one reference frame (which itself may be the result of a temporal prediction), the temporal predictions from the reference frames are weighted and combined.

Psychovisual Domain

The H.263 and H.264 standards support perceptual quantization through custom quantization tables. As an example of how to derive such custom quantization tables for the H.264 standard, Hu and Gibson (2005) explore the threshold at which human observers notice the test patterns that result from quantizing to zero ICT coefficients, one coefficient at a time. Based on small-sample subjective tests with five subjects, the authors show that using the nonuniform quantization matrices (derived by measuring thresholds to quantize the transform coefficients)

results in improved perceptual quality for several well-known video sequences.

Error Resilience

H.261. The H.261 standard recommends forced updating of pictures in intra mode at least once every 132 transmitted pictures, together with a *Bose-Chaudhuri-Hocquenghem* (BCH) forward error-correcting code in the encoder.

H.263. The H.263 standard supports an *enhanced reference picture selection* mode in which a decoder may reconstruct predicted pictures from alternate reference pictures stored in picture memories. The standard further recommends a BCH error-correcting code in the encoder.

H.264. The H.264 standard incorporates several error-resilience tools, including independent compression of slices. An encoder can specify that spatial prediction of macroblocks within temporally predicted slices use only macroblocks that were themselves spatially predicted in intra mode. Multiple reference picture support ensures that if transmission errors adversely affect a reference picture, other reference frames are available for reconstruction. *Flexible macroblock ordering* allows transmission of macroblocks in arbitrary order, spreading the impact of transmission errors over many frames instead of one. Data partitioning allows separation of syntax elements into different packets of data that may receive unequal protection. Transmission of redundant slices ensures replacement of primary slices that are corrupted or lost. Finally, a picture count separates the timing information from the picture number in case the timing information is corrupted or lost.

Rate Control

H.261

The H.261 standard Annex B recommends that a compliant encoder buffer its output and apply a *leaky-bucket* rate-control algorithm.

To understand how a leaky-bucket rate-control algorithm smoothes traffic bursts, consider a decoder buffer of capacity B bits. The initial buffer fullness parameter is $F \leq B$ bits. Let R be the peak rate (bps) at which bits enter the decoder buffer, which is initially empty. As bits arrive, the buffer fills up; when the buffer contains F bits, the decoder instantaneously removes all the bits in the buffer for processing. A compliant encoder sends no more bits until there is room in the buffer. The initial delay for the buffer to fill up is $D = F/R$, measured in seconds. Hence, the decoder receives a bit stream at a fixed rate, even though the buffer input receives a bit stream at variable rate.

The H.261 standard specifically recommends operating the encoder and decoder synchronously at the same clock frequency and CIF rate. Denoting the peak bit rate by R_{\max} kbps, the standard specifies the decoder buffer

size to be $\left\lceil \frac{4R_{\max}}{29.97} \right\rceil + 256$ kb. The decoder buffer is ini-

tially empty. The decoder examines the buffer at CIF intervals (approximately 33 msec) and if at least one complete coded picture is stored in the buffer, the decoder removes all the data corresponding to the earliest picture for processing. Immediately after removing the data, the buffer must contain less than $\left\lceil \frac{4R_{\max}}{29.97} \right\rceil$ kb.

H.263

The H.263 standard generalizes this leaky-bucket rate-control algorithm with decoder buffer size set to $\left\lceil \frac{4R_{\max}}{PCF} \right\rceil + P_{\max}$ where PCF denotes the *picture clock*

frequency (input picture rate) and P_{\max} denotes the maximum number of bits per picture that have been negotiated for use in the bit stream. The buffer is initially empty. The decoder examines the buffer at PCF intervals and, if at least one complete coded picture is stored in the buffer, the decoder removes all the data corresponding to the earliest picture for processing. Immediately after removing the data, the buffer must contain less than $\left\lceil \frac{4R_{\max}}{PCF} \right\rceil$ kb.

For the purpose of rate control, the H.263 standard defines a complete coded picture as an *I picture*, *P picture*, *PB picture*, or *improved PB picture*.

H.264

The H.264 standard Annex C specifies a *hypothetical reference decoder* (HRD) with a leaky-bucket rate-control algorithm, including a coded picture buffer, an instantaneous decoding process, a decoded picture buffer, and an output cropping process.

Milani et al. (2003) describe an iterative rate-control algorithm based on analysis by He and Mitra (2001), similar to that described by Tzannes (2002), and discussed in the section on rate control. In particular, the method of rate control modifies the quantization step size while coding different macroblocks according to a target fraction of transform coefficients quantized to zero to achieve the desired bit rate for the currently available bandwidth. To see how this works, let Δ denote the uniform quantizer step size and $p_x(a)$ denote the probability of observing a transform coefficient $x < a$ then Equation 49 yields $\rho(\Delta)$, the fraction of transform coefficients quantized to zero:

$$\rho(\Delta) = \sum_{|a| < \Delta} p_x(a) \quad (49)$$

An H.264 encoder may use fixed values of Δ , referred to as *integer quantization parameters*, denoted by $QP \in [0, 1, 2, \dots, 51]$. Note further that an H.264 encoder will not code any bits for a picture if all the transform coefficients are null for that picture, so Equation 50 describes an empirical linear relation with slope $-\lambda$ between the

observed bit rate denoted by R and the fraction of transform coefficients quantized to zero, denoted by ρ :

$$R(\rho) = \lambda(1 - \rho) \quad (50)$$

Equation 51 gives an empirical Laplacian form for the observed distribution $p_x(a)$ as reported by Milani et al. (2003) for I and P frames, where $\delta(a)$ is the Dirac delta function and α, β, γ are empirical constants:

$$p_x(a) = \gamma \exp(-\beta|a|^\alpha) \quad (51)$$

Similarly, Equation 52 gives an empirical Laplacian plus impulsive form for the observed distribution $p_x(a)$ as reported by Milani et al. (2003) for B frames, where α', β', γ' are empirical constants:

$$p_x(a) = \alpha' \delta(a) + \beta' \exp\left(-\frac{2|a|}{\gamma'}\right) \quad (52)$$

In Equation 51, normalization may determine the variable γ , while the mean and variance of the observed distribution $p_x(a)$ may determine the variables α, β . Similarly, in Equation 52, normalization may determine the variable β' , while the mean and variance of the observed distribution $p_x(a)$ may determine the variables α', γ' .

Let $I_m(x, y)$ and $\hat{I}_m(x, y)$ be respectively the original and predicted pixel value at position (x, y) in the 16×16 -pixel macroblock indexed by m in a frame having N_{MB} macroblocks. Equation 53 defines the current macroblock activity $act(m)$ and the current frame average activity $\langle act \rangle$:

$$\begin{aligned} act(m) &= \sum_{y=0}^{16} \sum_{x=0}^{16} |I_m(x, y) - \hat{I}_m(x, y)| \\ \langle act \rangle &= \frac{1}{N_{MB}} \sum_{m=0}^{N_{MB}} act(m) \end{aligned} \quad (53)$$

Equation 54 gives a quadratic approximation to the relations $\alpha(\langle act \rangle), \beta(\langle act \rangle), \gamma(\langle act \rangle)$:

$$\begin{aligned} \alpha(\langle act \rangle) &= \alpha_0(\rho) + \alpha_1(\rho) \cdot \langle act \rangle + \alpha_2(\rho) \cdot \langle act \rangle^2 \\ \beta(\langle act \rangle) &= \beta_0(\rho) + \beta_1(\rho) \cdot \langle act \rangle + \beta_2(\rho) \cdot \langle act \rangle^2 \\ \gamma(\langle act \rangle) &= \gamma_0(\rho) + \gamma_1(\rho) \cdot \langle act \rangle + \gamma_2(\rho) \cdot \langle act \rangle^2 \end{aligned} \quad (54)$$

Equation 55 gives an approximation to the relation $\alpha'(\langle act \rangle)$:

$$\alpha'(\langle act \rangle) = \alpha'_0(\rho) + \alpha'_1(\rho) \cdot \log(\langle act \rangle) + \alpha'_2(\rho) \cdot \log(\log(\langle act \rangle)) \quad (55)$$

Milani et al. (2003) report that they tabulated the observed coefficients $\alpha_i(\rho), \beta_i(\rho), \alpha'_i(\rho), \gamma'_i(\rho)$ as a function of ρ to yield a parametric approximation to the observed distribution $p_x(a)$.

Following Milani et al. (2003), a method for controlling the bit rate of a bit stream encoded by an H.264

encoder allocates $G_{k,0}$ bits to encode the GOP indexed by k . The method starts by allocating \bar{G} bits to encode the whole group of N at frame rate denoted by F_r and target bit rate denoted by R_b , as given by Equation 56:

$$\bar{G} = \frac{R_b \cdot N}{F_r} \quad (56)$$

Equation 57 shows how the method corrects for the difference between the target and actual number of bits used after coding the GOP indexed by $(k - 1)$, denoted by δG_{k-1} :

$$G_{k,0} = \delta G_{k-1} + \bar{G} \quad (57)$$

Equation 58 shows how the method selects a target bit rate T_n for the frame indexed by n in the current GOP, where n_i denotes the number of remaining frames of type $i \in \{I, P, B\}$ in the GOP, $K_{i,j}$ denotes the target bit ratio between frames of type i and frames of type j , where $i, j \in \{I, P, B\}$:

$$\begin{aligned} T_n &= K'_I \frac{G_{k,n}}{1 + K_{I,P} \cdot n_P + K_{I,P} \cdot K_{P,B} \cdot n_B}, \quad i \in \{I, P, B\} \\ K'_I &= K_{I,P} \cdot K_{P,B}, \quad K'_P = K_{P,B}, \quad K'_B = 1 \end{aligned} \quad (58)$$

Equation 59 updates the available number of bits for the frame indexed by $n + 1$ in the current GOP, denoted by $G_{k,n+1}$ after the current frame has been encoded by a number of bits, denoted by S_n :

$$G_{k,n+1} = G_{k,n} - S_n \quad (59)$$

The quantization parameter $QP \in [0, 1, 2, \dots, 51]$ drives the target bit rate T_n for H.264 encoders. Recalling Equation 50, the average fraction of transform coefficients quantized to zero for the frame indexed by n , denoted by ρ_n , is given by Equation 60, where the constant λ may be estimated from previously coded pictures (e.g., the frame indexed by $(n - 1)$ in the current GOP):

$$\rho_n = 1 - \frac{T_n}{\lambda} \quad (60)$$

Equation 49 determines the average quantization step size for the current picture indexed by the integer quantization parameter, denoted by $\langle QP_n \rangle$ from the average fraction of transform coefficients quantized to zero for the frame indexed by n , denoted by ρ_n , and the distribution $p_x(a)$, parameterized as shown in Equation 53 through Equation 55. Milani et al. (2003) recommend clipping the value of $\langle QP_n \rangle$ to the range $[\langle QP_{n-1} \rangle - 3, \langle QP_{n-1} \rangle + 3]$ to avoid producing objectionable quality differences between different picture zones. To smooth the coding distortion over different macroblocks, Milani et al. (2003) further correct the quantization parameter for each macroblock. Let

ρ_m^p denote the observed fraction of transform coefficients quantized to zero and B_m^p denote the number of bits used to code the current picture after coding the macroblock indexed by m of the frame indexed by n in the current GOP. For the target number of bits used to code the current picture, denoted by T_n , the remaining number of bits is $B_m^R = T_n - B_m^p$. Recalling Equation 60, Equation 61 gives the target remaining fraction of transform coefficients quantized to zero, denoted by ρ_m^R , to achieve the target number of bits, denoted by B_m^R , in a frame where total number of macroblocks is denoted by N_{MB} :

$$\rho_m^R = 1 - \frac{B_m^R}{\lambda} \cdot \frac{N_{MB}}{N_{MB} - m} \quad (61)$$

The H.264 standard relates the quantization step size, denoted by Δ , to the integer quantization parameter $QP \in [0, 1, 2, \dots, 51]$, according to Equation 62:

$$\Delta \approx 0.67 \cdot 2^{\frac{QP}{6}} \quad (62)$$

Defining $\delta k = \frac{0.67}{C} \cdot 2^{\frac{\langle QP_n \rangle}{6}}$, with the empirical constant

C set at $C = 3000$ to avoid creating strong variation in bit rate and visual quality across different macroblocks, Equation 63 gives the quantization parameter QP_{m+1} for the macroblock indexed by $(m + 1)$:

$$QP_{m+1} = \begin{cases} \langle QP_n \rangle + 3 & \text{if } 1 + 3 \cdot \delta k \leq k < +\infty \\ \langle QP_n \rangle + 2 & \text{if } 1 + 2 \cdot \delta k \leq k < 1 + 3 \cdot \delta k \\ \langle QP_n \rangle + 1 & \text{if } 1 + \delta k \leq k < 1 + 2 \cdot \delta k \\ \langle QP_n \rangle & \text{if } 1 - \delta k \leq k < 1 + \delta k \\ \langle QP_n \rangle - 1 & \text{if } 1 - 2 \cdot \delta k \leq k < 1 - \delta k \\ \langle QP_n \rangle - 2 & \text{if } 1 - 3 \cdot \delta k \leq k < 1 - 2 \cdot \delta k \\ \langle QP_n \rangle - 3 & \text{if } -\infty < k < 1 - 3 \cdot \delta k \end{cases} \quad (63)$$

To ensure that there are enough transform coefficients quantized to zero for ρ_m^p to be estimated, Milani et al. (2003) additionally set $QP_m = \langle QP_n \rangle$ until $B_m^p \geq 0.1 \cdot T_n$.

Miyaji et al. (2005) point out that assigning the same number of bits to each GOP, as recommended by Equation 56, requires a HRD buffer size equal to the largest number of bits generated by a frame in the GOP. An inappropriate choice of buffer size may lead to unacceptable delay, frozen video, or jerky motion. Furthermore, assigning the number of bits to each GOP using Equation 56 may lead to quality fluctuations because the picture information content is not considered.

Following Miyaji et al. (2005), Equation 64 gives an approximate quadratic relation between the *sum of absolute deviation* (SAD) of the prediction error in each macroblock, denoted by S , and the number of bits generated for the macroblock by an H.264 encoder using fixed values of quantization parameter without rate-distortion optimization:

$$bits = a \cdot S^2 + b \cdot S + c \quad (64)$$

Miyaji et al. (2005) determine the coefficients a, b, c by a method of least squares.

The H.264 standard supports *instantaneous decoding refresh* (IDR) pictures in which all slices are I or SI slices that cause the decoding process to mark all reference pictures as “unused for reference” immediately after decoding the IDR picture. An H.264 decoder can decode all following pictures without interframe prediction from any picture decoded before the IDR picture.

To avoid HRD buffer underflow, the number of bits of the current frame must be less than the HRD buffer level just before encoding the current frame and also larger than the number of bits that may be consumed by the following IDR frame. To avoid HRD buffer overflow, the HRD buffer level just before encoding the next frame must be lower than the maximum level at the next GOP boundary.

Miyaji et al. (2005) propose a method of allocating the number of bits to each frame according to the number of bits predicted by the observed value of SAD and a parameter related to the slope of the HRD buffer transition in a GOP, denoted by GW .

Let N denotes the number of frames in the GOP, B denote the maximum HRD buffer level, be denote the number of bits that are available for allocation to the first frame of the next GOP, Bh_i denote the HRD buffer level just before encoding the frame indexed by $i \in [1, 2, \dots, N]$, and b_i denote the number of bits used in encoding the frame indexed by i . Equation 65 gives the *underflow limit*, denoted by B_U , and the *overflow limit*, denoted by B_O :

$$\begin{aligned} B_U(i) &= \frac{be - (Bh_0 - b_0)}{N} i + (Bh_0 - b_0) \\ B_O(i) &= \frac{B - Bh_1}{N - 1} (i - 1) + Bh_1 \end{aligned} \quad (65)$$

Let $B_i(i)$ denote the line that equally divides the “safe area” between the underflow and overflow limits of the HRD buffer level. The HRD buffer level will progress around the line $B_i(i)$ if b_i is allocated to the frame indexed by i according to Equation 66, where BR denotes the maximum bit rate and FR denotes the maximum frame rate:

$$Bh_i - b_i + \frac{BR}{2FR} = B_i(i) \quad (66)$$

Define the parameter GW as the ratio of b_i to the average bit number for each frame. In accordance with Equation 66, Equation 67 gives the value of the parameter GW_i for the frame indexed by i :

$$GW_i = \frac{Bh_i - B_i(i)}{\frac{BR}{FR}} + \frac{1}{2} \quad (67)$$

Miyaji et al. (2005) determine the value of GW at the start of the GOP by using Equation 67 when $i = 2$.

To allocate the number of bits to each frame, Miyaji et al. (2005) use the frame SAD in accordance with the quadratic relation given by Equation 64, estimated for each fixed value of the quantization parameter, denoted by QP , so that Equation 68 gives the target number of bits for each frame, denoted by TB_i :

$$TB_i = f(SAD, QP) \quad (68)$$

Applying the weighting parameter $GW = GW_2$ to ensure that the HRD buffer level will progress around the line that equally divides the “safe area” between the underflow and overflow limits of the HRD buffer level, Equation 69 gives the target bit rate for each frame, denoted by T_i :

$$T_i = TB_i \bullet GW \quad (69)$$

Miyaji et al. (2005) further recommend allocating the number of bits for each macroblock in accordance with Equation 70, where TM_j and SAD_j are a target bit rate and observed SAD for the macroblock indexed by j :

$$TM_j = \frac{SAD_j}{\sum_j SAD_j} \bullet T_i \quad (70)$$

Equation 71 controls the cumulative number of bits generated from the first macroblock of the current frame to the macroblock indexed by j , denoted by BM_j , in terms of the average value of the quantization parameter QP for the preceding macroblocks, denoted by $\langle QP \rangle$ and a target value of QP for the current macroblock, denoted by QP_i :

$$2^{\frac{QP_i - \langle QP \rangle}{6}} = \frac{BM_{j-1}}{\sum_{k=1}^{j-1} BM_k} \quad (71)$$

Scalability

Many networks are subject to congestion. A method for reducing the impact of channel bandwidth fluctuations on video bit streams is to encode a base layer of video at a bit rate substantially below the channel capacity together with at least one enhancement layer; the combined base and enhancement layer bit streams result in video at a predetermined bit rate when sufficient bandwidth is available. Figure 34 shows a block diagram for a two-layer scalable video codec (after Ghanbari 1989).

Ghanbari (1992) reports an adapted H.261 two-layer video codec for transmitting *variable bit rate* (VBR) video over *asynchronous transmission mode* (ATM) networks. Ghanbari and Seferidis (1995) report a two-layer video codec where both the base layer and enhancement layer codecs are H.261 codecs with interframe coding in each layer. Ng et al. (1996) report a two-layer spatially scalable codec having an H.261 encoder in the base layer to provide a *constant bit rate* (CBR) QCIF-resolution bit stream, together with an enhancement layer having a pyramidal DCT encoder with perceptual quantization of residuals. The combination of base layer and enhancement layer bit streams provides a VBR CIF-resolution bit stream.

Qi et al. (2001) and Blaszkak et al. (2002) report fine granularity spatially scalable encoding with multiple enhancement layers for VBR video transmitted over ATM

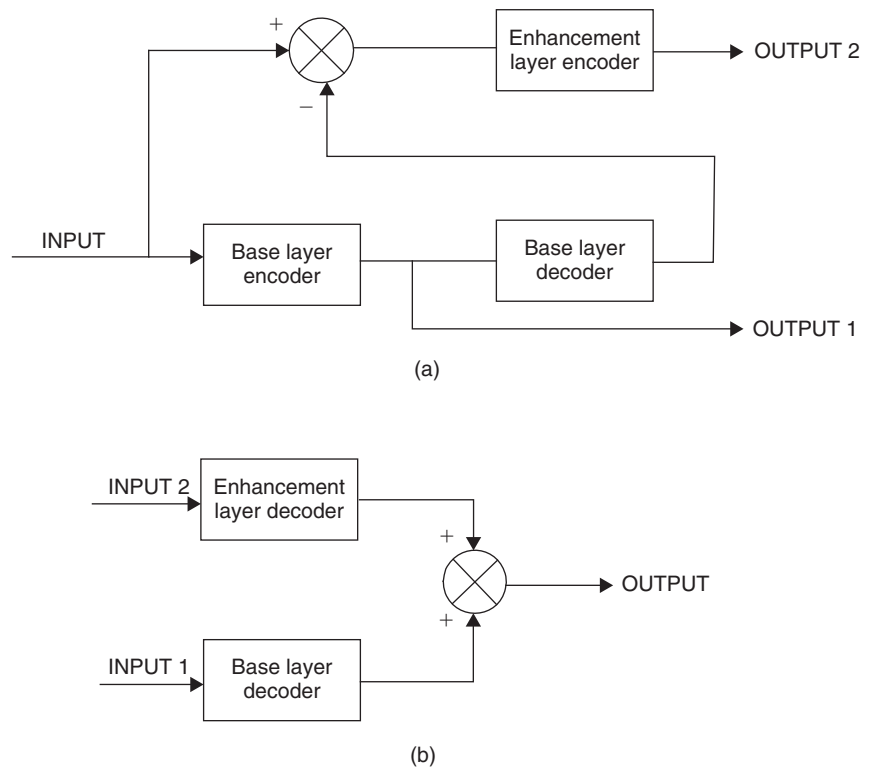

Figure 34: Block diagram of two-layer video codec (after Ghanbari, 1989)

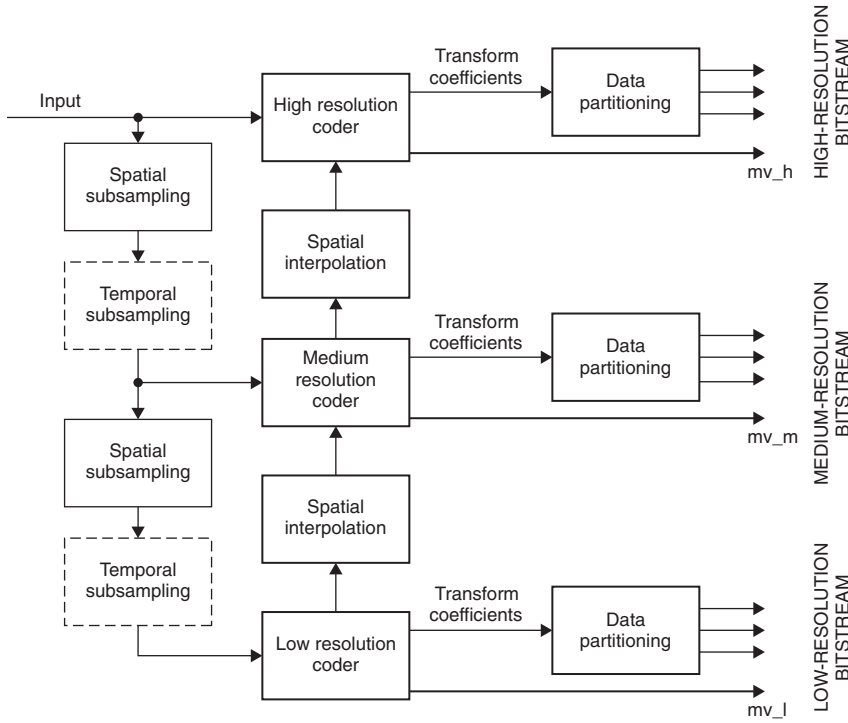

Figure 35: Block diagram of three-layer scalable coder (after Blaszk et al. 2002)

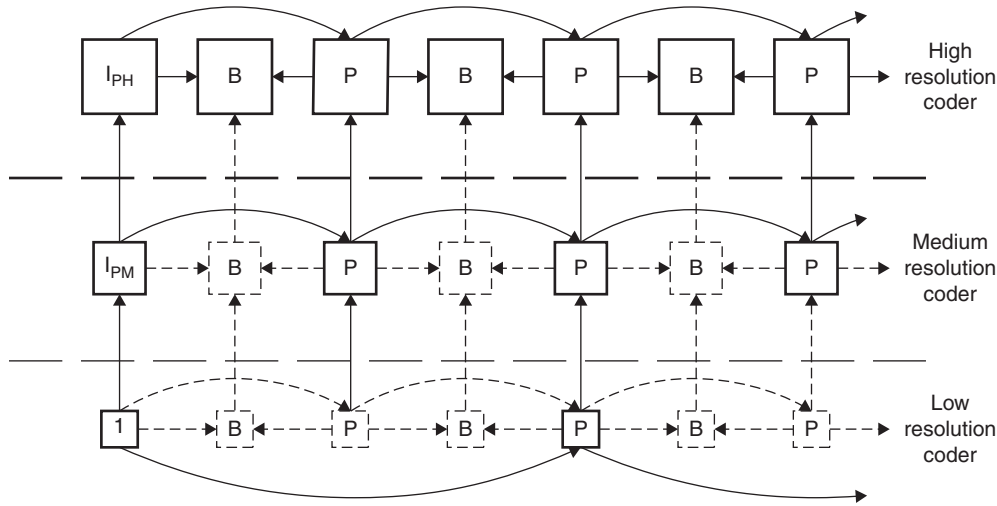

Figure 36: Exemplary image sequence for three-layer encoder (after Blaszk © 2002 IEEE)

and wireless networks. In particular, wireless networks are subject to fading and transmission error. Figure 35 shows a block diagram for the three-layer hybrid motion-compensated encoder with spatial and temporal scalability after Blaszk et al. (2002), who indicate that the medium- and high-resolution bit streams are appropriate for narrowband, middleband, and wideband networks, respectively.

Advantageously, all three coders may comply with video compression standards such as H.263. The proposed structure covers spatial resolutions QCIF for the low-resolution layer, CIF for the middle-resolution layer, and 4CIF for the high-resolution layer. The encoder estimates motion vectors mv_l for the low-resolution layer independent

of the motion vectors mv_m and mv_h estimated for the higher-resolution layers. Each layer may use fine granularity scaling to adapt to channel bandwidth fluctuations.

Figure 36 shows how the three-level encoder applies spatial and temporal subsampling by skipping frames.

Ugur and Nasiopoulos (2003) report a method for combining bit stream switching and fine granularity scalability for H.264 scalable video transmission that is compatible with standard H.264 encoders and decoders. In that paper, the H.264 fine granularity scalability mechanism has a base layer encoded at bit rate R_{base} and an enhancement layer encoded using bit-plane encoding up to a maximum bit rate R_{max} . The stream-switching mechanism

switches between a limited number of streams encoded at different bit rates at *switching predictive* (SP) frames rather than I frames, which allow identical reconstruction of frames even if they are predicted from different reference frames. In the combined system, fine granularity scalability accommodates low-bandwidth variations with respect to the base layer, while stream switching accommodates high-bandwidth variations that exceed a predetermined threshold.

The method determines the rates for each stream by optimizing the total distortion measure D given by Equation 33 for a given bandwidth R_{avail} , where R_i denotes the bit rate allocated to the base stream labeled by $i \in [1, 2, \dots, n]$, $R_1 = R_{min}$, $R_{n+1} = R_{max}$, $R_1 \leq R_2 \dots \leq R_{n-1} \leq R_n$ and D_i^{bp-j} denotes the distortion of the base stream labeled by i sending bp_j bit planes to the enhancement layer:

$$D = \sum_{i=1}^n \left(\sum_{R_{avail}=R_i}^{R_{avail}=R_{i+1}} D_i^{bp} \right) \quad (72)$$

Profiles

Annex A of the H.264 standard, which is currently the most advanced, flexible, and compressive ITU video codec, specifies seven capability profiles—*baseline*, *main*, *extended*, *high*, *high 10*, *high 4:2:2*, and *high 4:4:4*—and levels for these capability profiles. Each profile is a subset of H.264 capabilities, intended for a specific kind of application, as follows:

- *baseline profile* (BP), which is intended for video-conferencing and mobile applications that require the lowest cost and least computational resource;
- *main profile* (MP), which has been widely replaced by the high profile;
- *extended profile* (XP), which is intended for streaming video applications;
- *high profile* (HiP), which is intended for broadcast and disc storage applications, specially for high-definition television applications;
- *high 10 profile* (Hi10P), which is intended for broadcast and storage applications (and extends the high profile by supporting as many as 10 bits per sample of decoded picture precision);
- *high 4:2:2 profile* (Hi422P), which is intended for broadcast and storage applications (and extends the high 10 profile for professional applications that use interlaced video with support for the 4:2:2 chroma sampling format); and
- *high 4:4:4 profile* (Hi444P), which is currently a deprecated profile.

Table 1 shows a capability matrix for the above profiles.

Applications

High-Definition Video Storage

High-capacity optical disks developed by the Blu-Ray Disc Association and the DVD Forum can store 50 GB or

30 GB, respectively, on dual-sided 12-centimeter discs. By comparison, a dual-sided 12-centimeter *digital video disc* (DVD) can store only 17 GB. These high-capacity optical disk readers and writers use blue-violet lasers that operate at a 405-nanometer wavelength to read and write pits that are smaller and closer together than pits read and written by DVD readers and writers using red lasers that operate at a 650-nanometer wavelength.

As an example, the Blu-Ray Disc Association and DVD Forum have adopted the high profile of H.264 (together with the MPEG-2 and SMPTE 421M WMV 9 codecs discussed later in this chapter) for high-definition television content stored on high-capacity optical disks.

H.264 typically allows a Blu-Ray or high-definition DVD (HD-DVD) disk to store up to four hours of high-definition video encoded at 23 Mbps to 25 Mbps, compared to two hours for MPEG-2.

MPEG CODECS

The Motion Picture Experts Group (MPEG) started in 1988 as International Standards Organization (ISO) Working Group JTC1/SC29. The goal of MPEG is to develop standards for the digital compression of audiovisual signals. MPEG membership currently exceeds 300 experts.

MPEG-1

The MPEG team published the MPEG-1 standard in 1993 as 11172-2 (ISO/IEC 1993), with four updates issued between 1996 and 2006. The standard specifies a decoding process for moving pictures and associated audio. MPEG-1 is primarily applicable to noninterlaced digital video formats preferably having a *standard intermediate format* (SIF) of 288 lines of 352 pixels with picture rates approximately 24 hz to 30 hz at bit rates up to approximately 1.5 Mbps and visual quality similar to the well-known *video home system* (VHS).

The MPEG-1 standard assumes a video input in $YCbCr$ color space with 4:2:0 sampling for spectral redundancy reduction. Reminiscent of JPEG, the recommended method for spatial redundancy reduction is 8×8 -pixel block-based DCT coding with visually weighted scalar quantization, zigzag coefficient ordering, differential encoding of DC coefficients between blocks, and run-length coding of AC coefficients quantized to zero followed by *variable length code* (VLC) entropy coding. MPEG-1 defines blocks as 8×8 -pixel regions and macro-blocks as 16×16 -pixel regions.

The MPEG-1 standard recommends motion-compensated transform coding of pixel value differences between observed and predicted pictures. It is the responsibility of the encoder to determine appropriate motion vectors, and the standard does not recommend any method for doing so.

MPEG-1 supports *intra* (I), *predicted* (P), *bidirectionally predicted* (B), and *DC-coded* (D) pictures. MPEG-1 encoders never use B frames as references for prediction. D pictures are intra coded with DC transform coefficients but no AC transform coefficients to facilitate fast-forward and reverse playback operations. The standard recommends a

Table 1: H.264 Profile Capability Matrix

	Baseline	Extended	Main	High	High 10	High 4:2:2	High 4:4:4
I and P slices	X	X	X	X	X	X	X
B slices		X	X	X	X	X	X
SI and SP slices		X					
Multiple reference frames	X	X	X	X	X	X	X
Loop deblocking filter	X	X	X	X	X	X	X
CAVLC entropy coder	X	X	X	X	X	X	X
CABAC entropy coder			X	X	X	X	X
Flexible macroblock order	X	X					
Arbitrary slice order	X	X					
Redundant slices	X	X					
Data partitions		X					
Interlaced pictures			X	X	X	X	X
4:2:0 chroma format	X	X	X	X	X	X	X
4:0:0 monochrome format				X	X	X	X
4:2:2 chroma format						X	X
4:4:4 chroma format							X
8-bit sample depth	X	X	X	X	X	X	X
9-and 10-bit sample depth					X	X	X
11-and 12-bit sample depth							X
8 × 8 and 4 × 4 adaptive transforms				X	X	X	X
Quantization scaling matrices				X	X	X	X
Quantization parameters for C _b and C _r separately				X	X	X	X
Residual color transform							X
Predictive lossless codes							X

subset of the coding parameters known as the *constrained parameters*, which are defined as follows:

- horizontal picture size ≤ 768 pixels,
- vertical picture size ≤ 576 lines,
- picture area ≤ 396 macroblocks,
- picture rate ≤ 30 Hz,
- pixel rate $\leq 396 \times 25$ macroblock/second,
- motion vector range $\leq [-64, \dots, 63.5]$ pixels at half-pixel accuracy,
- input buffer size $\leq 327,680$ bits, and
- bit rate ≤ 856 kbps at near constant bit rate.

An encoder may skip macroblocks in P and B pictures that have no associated motion vectors or for which the motion vector is zero. MPEG-1 recommends that the encoder force the use of an intra-coded macroblock at least once every

132 times that it is encoded in a P picture without an intervening I picture, as recommended by the H.261 standard to control the accumulation of floating-point inverse DCT mismatch error. Because the output bit rate is variable, MPEG-1 recommends that a compliant encoder implement a leaky-bucket rate-control buffer, which is specified as the MPEG-1 standard *video buffer verifier* (VBV).

The two-layer scalable video codecs developed by Ghanbari (1992), Ghanbari and Seferidis (1995), and Ng et al. (1996), discussed in the section on scalability, can be adapted for MPEG-1 scalable video coding.

Applications of the MPEG-1 standard include *video compact disc* (VCD) compression and decompression.

MPEG-2

Developed from 1990 to 1995, the MPEG-2 standard is widely deployed and currently jointly standardized by ITU and MPEG with multiple updates as H.262 and ISO/IEC

Table 2: Display and Transmission of an Exemplary Group of 12 MPEG-2 Intra (I), Predicted (P), and Bidirectional (B) Pictures

Display	B	B	I	B	B	P	B	B	P	B	B	B
Frame	1	2	3	4	5	6	7	8	9	10	11	12
Transmit	I	B	B	P	B	B	P	B	B	P	B	B
Frame	3	1	2	6	4	5	9	7	8	12	10	11

13818-2:2000. The MPEG-2 standard, based on the DCT, shares many features with the H.264 standard, operating on noninterlaced and interlaced video; it delivers approximately half as much compression as H.264 using considerably less computational resources. MPEG-2 supports scalable compression in which a compliant decoder can extract useful video from portions of a compressed bit stream. MPEG-2 operates on pictures in YC_bC_r color space with 4:2:0, 4:2:2, and 4:4:4 sampling formats using the 8×8 -pixel DCT, and it accepts one motion vector per 16×16 -pixel macroblock at half-pixel accuracy. MPEG-2 is capable of encoding standard definition television at bit rates from approximately 3 Mbps to 15 Mbps and high-definition television at approximately 15 Mbps to 30 Mbps.

Table 2 shows the relationship between an exemplary group of I, P, and B pictures. The different picture types typically occur in a repeating GOP sequence. I pictures are coded using information only from that picture. P pictures are coded using forward prediction from previous I or P pictures. A compliant encoder codes B pictures from previous and succeeding frames using I or P pictures (but not other B pictures, which H.264 allows). This, in turn, implies that the encoding order may be markedly different from the display order. Because decoding B pictures requires both past and future pictures to be available, the presence of B pictures adds considerably to the encoder delay.

The MPEG-2 standard specifies five capability profiles: *simple*, *main*, *SNR scalable*, *spatially scalable*, and *high*. Levels for each capability profile are also specified. Each profile is a subset of MPEG-2 capabilities as follows:

- *Simple profile* supports noninterlaced video in 4:2:0 sampling format without B pictures.
- *Main profile* supports noninterlaced and interlaced video in 4:2:0 sampling format with I, P, and B pictures.
- *SNR scalable profile* provides two layers with the same spatial resolution but different picture quality.
- *Spatially scalable profile* provides two layers with arbitrary spatial resolution and picture quality, each coded without regard for the other.
- *High profile* supports interlaced and noninterlaced video in the 4:2:2 sampling format.

The two-layer scalable video codecs developed by Ghanbari (1992), Ghanbari and Seferidis (1995), and Ng et al. (1996) can be adapted for MPEG-2 scalable video coding. The multiple enhancement layer scalable video codec reported by Blaszk et al. (2002) can also be adapted for MPEG-2 scalable video coding.

The MPEG-2 simple profile at main level requires only I and P frames, thus reducing encoding delay. Videoconferencing is an appropriate application for the MPEG-2 simple profile (Tudor 1995), although the H.261, H.263, and H.264 standardized codecs are more widely used for that purpose.

MPEG-4

The MPEG Web site provides detailed information about MPEG standards and includes an overview. In particular, H.264 is the ITU name for the ISO/ITU joint standard MPEG-4 Part 10.

MPEG-4 is an extensible toolbox of algorithms that addresses the coding of audiovisual objects throughout an extended bit range from approximately 5 bps to more than 1 Gbps. The standard addresses video compression together with audio and systems elements.

MPEG-4 standardizes only bit stream syntax and decoder algorithms. Standardization of H.264 has now overtaken the MPEG-4 visual codec IEEE:14496-2 based on the DCT (ISO/IEC 2004). However, the Koenen (2002) overview of the MPEG-4 standard illustrates concepts such as encoding scenes containing visual objects and sprites, which the H.264 standard does not directly incorporate. In particular, MPEG-4 allows a *shape-adaptive discrete cosine transform* (SA-DCT) to encode visual objects of arbitrary shape (not just rectangles) together with texture. SA-DCT calculations use predefined orthonormal sets of *one-dimensional discrete cosine transform* (1D-DCT) functions within an 8×8 -pixel block (Sikora 1995). A set of 1D-DCT functions of the same length as each column encodes a visual object of arbitrary shape in the vertical direction. Next the algorithm shifts the visual object's rows to the left border of the 8×8 -pixel block and a set of 1D-DCT functions of the same length as each row encodes the object. This technique results in a block with as many DCT coefficients as the visual object has pixels. A compliant decoder requires contour information to decode the coefficients. This technique is appropriate for applications such as nonlinear editing of video objects when an editor selects a visual object's contours by manual intervention or downstream keying.

The MPEG-4 standard additionally supports coding audiovisual objects, including static and dynamically generated *sprites*, which are still images representing backgrounds visible throughout a scene of a video sequence. Figure 37 depicts an audiovisual scene containing scrolling text, audio, background sprite, arbitrarily shaped video, and graphics.

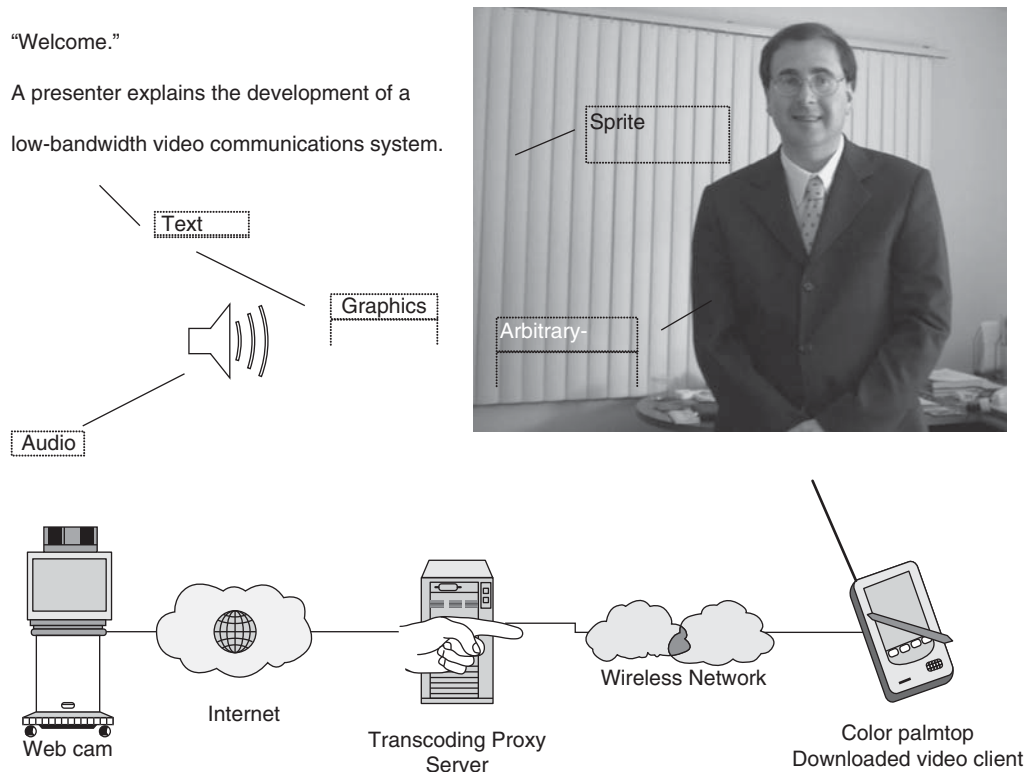

Figure 37: Audiovisual scene containing scrolling text, audio, background sprite, arbitrarily shaped video, and graphics

The MPEG-4 standard currently supports scalability of visual objects through the profiles illustrated in Table 3.

The multiple enhancement layer scalable video codec reported by Blaszk et al. (2002), as discussed earlier in the section on scalability and JPEG codecs, can also be adapted for MPEG-4 scalable video coding. The MPEG-4 standard additionally supports *visual object plane* (VOP) spatial and temporal scalability via methods for generalized scalable coding together with methods for fine granularity scalable coding. In particular, the MPEG-4

standard supports spatial temporal scalability of rectangular VOPs and temporal scalability of arbitrarily shaped VOPs. The MPEG-4 standard supports fine granularity scalable coding via truncation of bit streams coding DCT coefficient bit planes.

MPEG-7

The MPEG-7 standard 159383 (ISO/IEC 2002) defines a multimedia content description interface to provide fast

Table 3: MPEG-4 Standard Scalable Profiles

Profile	Objects	Use
Simple visual	Rectangular video objects	Mobile networks
Simple scalable visual	Temporal and spatial scalable objects	Internet
Core visual	Arbitrarily shaped and temporally scalable	Internet multimedia
N-bit visual	Core visual, but 4–12 bits pixel depth	Surveillance
Scalable texture visual	Spatial scalable coding of still (texture) objects	Games, still cameras
Core scalable	Temporal and spatially scalable arbitrarily shaped objects	Internet, mobile, broadcast
Advanced scalable texture	Arbitrarily shaped texture and still images	Image browsing
Advanced core	Arbitrarily shaped video objects and still image objects	Interactive multimedia streaming over Internet
Fine granularity scalability	Truncation of bit stream at any bit position to adapt delivery quality as required	Any

and efficient methods for searching, filtering, and identifying multimedia content. In particular, Part 3 of the MPEG-7 Standard focuses on metadata for visual content such as still images, video, and three-dimensional models.

Part 3 of the MPEG-7 Standard specifies the following elements:

- *Description schemes* describe entities or relationships that pertain to multimedia content. They specify the structure and semantics of their components, which may be description schemes, descriptors, or data types.
- *Descriptors* describe features, attributes, or groups of attributes of multimedia content.
- *Data types* are the basic reusable data types employed by description schemes and descriptors.
- *Description definition language* defines description schemes, descriptors, and data types by specifying their syntax and allows their extension (currently based on extensible markup language, or XML).
- System tools that support delivery of descriptions and multiplexing of descriptions with multimedia content, synchronization, and file format.

Part 3 of the MPEG-7 standard provides the following visual description tools:

- *basic structures*, such as descriptor containers (grid layout, time series, and multiple view), together with basic supporting tools (temporal interpolation and a spatial two-dimensional coordinate system);
- *visual features*, such as
 - *color*, such as color feature descriptors (dominant color, scalable color, color layout, color structure, and group of frames, group of pictures color descriptor, together with color supporting tools (color space and color quantization);
 - *texture*, such as homogeneous texture, texture browsing, and edge histogram;
 - *shape*, such as region shape, contour shape, and 3D shape;
 - *motion*, such as camera motion, motion trajectory, parametric motion, and motion activity;
 - *localization*, such as region locator and spatio-temporal locator; and
- other structures, such as face recognition.

Schafer et al. (2000) suggest using metadata currently defined in the MPEG-7 standard to improve coding efficiency. In particular, if the production process generates information about cut and fade transitions, an encoding strategy can switch off predictive coding when no motion compensation model would be useful. If the production process provides visual object metadata from an editing or chroma color process (such as blue screen), an encoding strategy can provide for separate coding of moving objects, background, and transparent layers—which is especially useful when a motion compensation model is unable to predict the appearance or disappearance of moving objects. If the production process provides

camera motion metadata, this will facilitate global motion compensation coding of MPEG-4 sprites. Finally, an encoding strategy may use information about color and texture histograms or distribution to adjust bit allocation or quantizer values.

OTHER CODECS

This section of the chapter discusses proprietary and other codecs.

SMPTE 421M (WMV 9)

Microsoft proposed Windows Media Video 9 (WMV9) codec, renamed VC-1. In 2006, the Society of Motion Picture and Television Engineers (SMPTE)* standardized this codec as SMPTE 421M (SMPTE 2006).

SMPTE 421M competes with the H.264 standard based on the 8×8 -pixel DCT, with particular strength in compressing interlaced content widely available to the broadcast and video industries. Although the SMPTE 421M and H.264 are broadly similar standards, specific differences between SMPTE 421M and H.264 include overlapped transforms, intensity compensation, display metadata with so-called pan-and-scan windows, and leaky-bucket rate control.

Overlapped transforms reduce blocking artifacts by using coefficients from neighboring blocks in the block reconstruction. SMPTE 421M emulates an overlap transform by smoothing 8×8 -pixel block boundaries before applying an in-loop deblocking filter. Consider the three image blocks depicted in Figure 38.

The overlap transform algorithm filters all of the reconstructed pixels in the four-pixel wide boundary (shown crosshatched in Figure 38), applying a filter to pixels at vertical edges (such as a_0 , a_1 , b_1 , and b_0) followed by pixels at horizontal edges (such as p_0 , p_1 , q_1 , and q_0). In particular, the algorithm filters the 2×2 corner pixels (shown as a rectangle in Figure 39) in both vertical and horizontal directions. Equations 73 and 74 define the overlap smoothing filter, which filters input pixel values $[x_0 \ x_1 \ x_2 \ x_3]$ to output pixel values $[y_0 \ y_1 \ y_2 \ y_3]$:

$$\begin{bmatrix} y_0 \\ y_1 \\ y_2 \\ y_3 \end{bmatrix} = \frac{1}{8} \left\{ \begin{bmatrix} 7 & 0 & 0 & 1 \\ -1 & 7 & 1 & 1 \\ 1 & 1 & 7 & -1 \\ 1 & 0 & 0 & 7 \end{bmatrix} \begin{bmatrix} x_0 \\ x_1 \\ x_2 \\ x_3 \end{bmatrix} + \begin{bmatrix} r_0 \\ r_1 \\ r_0 \\ r_1 \end{bmatrix} \right\} \quad (73)$$

$$\begin{aligned} r_0 &= 4, \ r_1 = 3 \text{ (odd-numbered rows and columns)} \\ r_0 &= 3, \ r_1 = 4 \text{ (even-numbered rows and columns)} \end{aligned} \quad (74)$$

* The SMPTE is a multidisciplinary organization focused on developing standards for the motion imaging industry. Started in 1916 as the Society for Motion Picture Engineers, the society embraced television engineering in 1950.

Figure 38: Overlap smoothing of 8×8 -pixel blocks

Figure 39: Images of frame numbered 1251 from *The Emotion of Space* encoded by (a) the MPEG-4 codec after flipping bits, (b) the VP70 codec software before flipping bits, and (c) the VP70 codec software after flipping bits

The SMPTE 421M standard recommends methods for detecting fade sequences and compensating luminance in fade sequences for efficient coding. Optional display metadata provide a compliant decoder with information such as the geometry of decoded pictures, together with pan-and-scan windows, which are subpictures that provide alternate display formats such as a 4:3 aspect ratio picture-in-picture display within an anamorphic 16:9 aspect ratio picture.

Many proprietary codecs have not yet received formal standardization. Of current interest are RealVideo (Real Networks), TrueMotion VP7 (On2 Technologies), and EuclidVision (Euclid Discoveries).

RealVideo-10

Real Networks released RealVideo-1 in 1997, based on a proprietary implementation of the H.263 standard. The technical summary for the current version (RealVideo-10) describes a scalable block-based transform coder with spatial prediction, temporal prediction, motion compensation, and psychovisual filtering (Real Networks 2003). RealVideo-10 relates to U.S. patents 5,854,858 and 5,917,954 granted to Girod et al. These patents disclose a multiresolution coder in which the encoder can decide to provide low-resolution pictures for coding by a 4×4 -pixel DCT after averaging 2×2 -pixel regions in the input pictures. Coding blocks by a 4×4 -pixel DCT requires considerably less computational resource than coding blocks by an 8×8 -pixel DCT. The encoder inserts the 4×4 -pixel DCT coefficients into the lowest 4×4 coefficients of the corresponding 8×8 -pixel blocks in the input pictures, with the remaining 48 coefficients set to zero for each 8×8 -pixel block.

TrueMotion VP7

U.S. Patent 7,027,654 granted to Ameres et al. and assigned to On2 Technologies discloses a video compression system for vector architectures such as Intel's multimedia extensions. The disclosed encoder includes a motion estimator; a block-based 8×8 DCT; a quantizer; a variable length encoder; and a loop filter for smoothing block edges. The encoder includes a deblocking filter and an edge-enhancing deringing filter, both designed for implementation on vector processors. The deblocking filter uses simple linear calculations and one-dimensional filters to remove blocking artifacts and gather information for use by the edge-enhancing deringing filter (similar to a symmetric neighborhood filter).

The TrueMotion VP7 white paper (On2 Technologies 2005) suggests that the proprietary codec implements 4×4 -pixel transforms, improved motion compensation allowing the representation of complex patterns of motion, and second-order coding of transform DC coefficients. The VP7 codec also implements a motion vector filter, deblocking and deringing filters, a scene change detector for automatic key frames, and a method for adapting to changes in light level.

EuclidVision

Euclid Discoveries claims to have developed an object-based coding technology that leverages the MPEG-4 standard. Note that the MPEG-4 standard supports object-based video coding, which is especially useful when the video sequence is a composite formed by an editor from known video objects stored separately in a video database.

In principle, if the video objects identified in a scene have substantially different statistical characteristics, such as “talking head” video on a smooth featureless background, object-based coding methods provide substantial improvements in compression ratio and video quality in comparison with picture-based coding methods.

Euclid Discoveries has published five provisional patent applications related to object-based video coding. The most recently published application, U.S. 2006/0233448 to Pace et al., apparently discloses an apparatus and method for processing video data. By segmenting video pictures into video objects, the method allows prioritization of these objects for separate compression. The method detects and tracks objects through successive pictures, together with specific features of these objects—such as the eyes or nose in a face—via multiresolution analysis of the spatial gradient of optical flow. The method also performs motion compensation by analyzing the translation, rotation, and scaling of a mesh of vertices that connect discrete regions for each picture (similar to a wireframe model). In the preferred embodiment, the method determines the motion displacement for each vertex relative to an interpolated polygon neighborhood by block-based matching in a rectangular tile neighborhood. The method additionally removes outliers by a robust process such as the RANSAC algorithm (Fischler and Bolles 1981).

EVALUATION

Consider selecting a commercially available video codec for deployment in a hypothetical wireless videophone system operating over a 384 kbps link. To be acceptable, a solution must be cost-effective, the visual quality acceptable to viewers, the encoding and decoding latency each less than approximately 0.25 second, and the battery life maximized. For this example, cost-effectiveness, latency, and battery life are more important factors than visual quality. If the wireless channel degrades through network congestion, rain fading, or multipath propagation, then the reconstructed visual quality must degrade gracefully. The solution must be capable of yielding an average bit rate within 5 percent of the target bit rate and robustly decode video transmitted over a channel that has a relative error rate up to approximately 10^{-5} per second after error correction.

The requirement for graceful degradation of visual quality suggests a solution based on a spatially and temporally scalable codec, effective at bit rates up to approximately 384 kbps (typically 360 kbps when audio tracks are considered). Of the codecs discussed in this chapter, these requirements imply that the only candidates are H.264, H.263, MPEG-4, Motion JPEG 2000, VC-1, RealVideo-10, and TrueMotion VP7 (EuclidVision is not currently widely available). The MPEG-2 standard scalable profiles are appropriate only for target bit rates from approximately 3 Mbps to 15 Mbps, whereas MPEG-1, Motion JPEG, and Motion JPEG-LS do not recommend scalable solutions.

In particular, consider real-time encoding of *The Emotion of Space*, frames 1230 to 1679, at 15 fps in 24-bit color on a hypothetical 624-MHz processor with 32 MB memory. Although the architectures are not directly

comparable, consider benchmarking commercially available codecs on a Windows XP Professional workstation with a dual 1.7-GHz processor and 1 GB memory.

Selecting a Commercially Available Video Codec for Deployment

For this example, the candidates are the H.264, H.263, MPEG-4 Visual and Motion JPEG 2000 implemented by Lead Tools, SMPTE 421M implemented by Microsoft as WMV9 in Windows Media Encoder Series 9, RealVideo-10 implemented by Real Networks in Real Producer, and True Motion software version 0 (VP70) implementing the VP7 codec developed by On2 Technologies. Each implementation has a small number of user-adjustable configuration parameters. Table 4 tabulates the experimental results.

To maximize encoding speed and battery life, the H.264 codec configuration was constant bit rate with target set to 360 kbps, output frame rate set to 15 fps, entropy coding type set to CAVLC (rather than CABAC), and motion estimation set to the “very fast” option. Because rate control appears not to be effective unless the group of pictures comprises at least two pictures, the GOP structure is one P picture between successive I pictures and no B pictures to minimize latency. The observed visual quality and latency are acceptable. The bit rate is more than 5 percent above the target bit rate, and the compression speed is about half real-time using 2.6 times the platform CPU and 1.7 times the platform memory.

To maximize encoding speed and battery life, the H.263 codec configuration was constant bit rate with target set to 360 kbps and output frame rate set to 15 fps. Every frame is a key frame, to minimize latency, with quality improved by selecting the deblocking filter and advanced intra coding options. The visual quality is slightly blocky with corona around strong visual edges and slight flickering with soft contrast. Although latency is acceptable, visual quality is unacceptable. The average bit rate is quite far from the target bit rate, perhaps requiring improved rate control. The compression speed is some five times faster than real time using approximately 2.2 times the platform CPU and one times the platform memory.

To maximize encoding speed and battery life, the MPEG-4 codec configuration was fast motion vector search, without four motion vectors per macroblock or half-pixel motion vector accuracy. The configuration selects one P picture between every two I pictures to minimize latency. By experiment, quality factor $Q = 10$ yields average bit rate 492 kbps bit rate, whereas $Q = 12$ and $Q = 11$ yield 307.8 kbps and 325 kbps average bit rate, respectively. Adopting $Q = 11$, the visual quality is slightly blocky with slight flickering. The visual quality and latency are acceptable. The average bit rate would benefit from improved rate control. The compression speed is approximately 3.75 times faster than real time using 2.99 times the platform CPU and less than the platform memory.

The Motion JPEG 2000 codec configuration was 77:1 compression for 360-kbps target bit rate. The average bit rate is 389 kbps. The visual quality is slightly blurry with slight flickering. The visual quality and latency are acceptable. The average bit rate is within 8 percent of the target bit rate, and the codec could benefit from slightly improved rate control. The compression speed is

Table 4: Video Compression Experimental Results

Codec	Configuration	Average bit rate (kbps)	Elapsed time (sec)	Peak processor utilization (%)	Peak memory (Mb)	Average PSNR (dB)	VQM general model (DSIS)	Latency (sec)
H.264	CBR CALVC Very fast GOP = 2 (IPIP)	418	63	48	54	20.69	3.64	0.13
H.263	Deblocking filter Advanced intra coding GOP = 1	209	6	40	31	18.45	2.7	0.2
MPEG-4 visual	Q = 11Fast search GOP = 21 motion vector per macroblock Full pixel accuracy	325	8	55	28	20.62	3.89	0.13
Motion JPEG 2000	77:1	389	23	48	24	20.71	3.86	0
WMV9	384 kbps	403.9	31	91	120			
RV40	384 kbps Normal video One-pass	362	25	81	39			
VP70	Live encoding Target = 678 kbps Speed 8 Sharpness 4 Noise reduction off Undershoot 95% Overshoot 105% Quantizer [4, 56] Prebuffer = 0 Optimal buffer = 0 Max buffer = 0	362	9	48	43	22.98	4.16	0.13

approximately 30 percent faster than real time using 2.5 times the platform CPU and approximately 75 percent of the platform memory.

The WMV9 codec configuration was 384-kbps target bit rate. The average bit rate is 403.9 kbps. The visual quality is very good. The average bit rate (measure by file size) is more than 5 percent above the target bit rate. The compression speed is approximately real time using 5.2 times the platform CPU and 3.75 times the platform memory. Multiple compression layers support graceful degradation but were not configured for this experiment.

The RealVideo-10 codec configuration selects a 384-kbps audience (350 kbps video) for single-layer video without audio and “normal video” with one-pass video encoding. The visual quality is very good. The average bit rate is within 5 percent of the target bit rate. The compression speed is 17 percent faster than real time using approximately 5.4 times the platform CPU and 1.2 times the platform memory. Multiple compression layers support graceful degradation but were not configured for this experiment.

The VP70 codec configuration is 384 kbps CBR for live encoding, with speed 8, sharpness 4, noise reduction off, undershoot 95 percent, overshoot 105 percent, quantizer [4, 56], prebuffer 0, and buffer 0. By experimentation,

setting the target bit rate to 678 kbps yields a 362-kbps file. The visual quality is very good with acceptable latency. The compression speed is 3.3 times faster than real time using 2.6 times the platform CPU and 1.34 times the platform memory. An optimized implementation with better rate control or a 34 percent increase in platform memory could make VP70 a stronger candidate. Hence, MPEG-4 and VP70 were selected for subsequent bit-error resilience tests.

Bit-Error Resilience Tests

A simplified bit-error resilience test flipped bits with uniform random distribution for 10^{-5} of the bytes in each output file. The MPEG-4 bit-flipped output file played to completion in Windows Media Player 9 without noticeable bit error-induced artifact. The VP70 bit-flipped output file played to completion in Windows Media Player 9 with some frames having rectangular regions with changed colors, such as frame 1251. Figure 39 shows gray-scale images of frame 1251 (a) encoded by the MPEG-4 codec but not visibly damaged by flipping bits, (b) frame 1251 encoded by the VP70 codec before flipping bits, and (c) the VP70 codec after flipping bits.

Table 5 tabulates the measured visual quality metrics before and after flipping bits.

Table 5: Visual Quality Metric for *The Emotion of Space*, Frames 1230 to 1679*

Codec	Average PSNR (dB)	VQM General Model (DSIS)
MPEG-4	20.62	3.89
MPEG-4 (after)	20.58	3.85
VP70 (before)	22.98	4.16
VP70 (after)	20.57	3.52

* Encoded by MPEG-4 and VP70 codec software before and after flipping bits.

In this educational example, the MPEG-4 codec would be more likely than not selected for deployment on technical grounds.

CONCLUSION

This chapter has discussed principles by which digital video signals are compressed, and we have reviewed applicable standards developed by JPEG, MPEG, ITU, and SMPTE, together with proprietary codecs developed by Microsoft, Real Networks, On2 Technologies, and Euclid Discoveries. The chapter provided a simple example of codec evaluation based on commercially available codecs for real time communications.

GLOSSARY

Foveation point: The point at which the eye is looking.

Frame: An image from a video sequence.

Lossless: A reversible and exact process.

Lossy: An irreversible and approximate process.

Minimum coded unit (MCU): The minimum amount of image data that a coder can code.

Picture clock rate: The input picture rate.

Scene: A sequence of frames.

INTRODUCTION

Audible signals such as speech and music are acoustic sound waves. They are analog waveforms characterized by pressure changes that propagate through a medium such as air or water. The waveforms are created by a vibrating source such as a loudspeaker or musical instrument and received by a receptor such as a microphone diaphragm or eardrum. An example of a simple waveform is a pure tone. It consists of a periodic signal that repeats its waveform shape many times per second. The number of repetitions per second is its *frequency* and is measured in hertz (Hz). Audible tones are typically in a range of 20 to 20,000 Hz, which is referred to as the *bandwidth* of audible signals. The tone will create a sound pressure displacement that is related to its amplitude. Signals with high amplitude will sound louder than signals with low amplitude, and the range from soft to loud is called *dynamic range*. Complex sounds (e.g., the sound of a piano or speech) consist of a combination of many tones of different frequencies and amplitudes that vary over time.

Using a microphone, one can capture the acoustic waveform and convert this into an electric signal. This electric signal or waveform can be converted back to an acoustic signal by using a loudspeaker. To represent this analog waveform as a digital signal, it is necessary to find a numerical representation that preserves its characteristics. The process of converting an analog signal to a digital signal is usually referred to as *digitization*. A digital representation of audio and speech signals has many advantages. It is easier to combine with other media such as video and text, and it is easier to make the information secure by encrypting it. Digital representations also enable procedures to protect against impairments when transmitting the signals over error-prone communication links. The main disadvantage is that straightforward digitization of analog signals results in data rates that require much more capacity of the physical channel than the original analog signal. Before we provide examples of this dilemma, let us first take a look at the principles of digitization.

To digitize an analog audio signal, it is necessary to sample the signal at discrete instances of time at a rate equivalent to or more than twice the highest bandwidth that exists in the signal (this is the *sampling* or *Nyquist*

theorem). The frequency that the signal is sampled with is referred to as the *sampling frequency*. Typical sampling frequencies for speech signals are between 8 and 16 kHz, while for music signals ranges between 16 and 48 kHz are more common. To get a digital representation, the sample values need to be represented with a discrete set of numbers represented by a binary code. This process is referred to as *quantization*. In contrast to sampling, which allows the perfect reconstruction of the original analog waveform, quantization will introduce errors that will remain after reconstructing the analog signal. The *quantization error* (defined as the difference between the analog sample value and its discrete value) can be made smaller by using more bits per sample. For example, an 8-bit number allows $2^8 = 256$ different values, while a 16-bit number allows 65,536 different values. For speech, signals between 8 and 16 bits per sample are adequate, while for high quality music signals 16 to 24 bits per sample are commonly used.

The digitization process of sampling and quantization as described above is referred to as *pulse coded modulation* (PCM). The total bit rate for a PCM signal is given by:

$$\text{sampling rate} \times \text{number of bits per sample} \\ \times \text{number of audio channels}$$

For a stereo signal on a compact disc (CD), this means $44,100 \times 16 \times 2 \times 1,411,200$ bits per second (1411 Mb/s). As illustrated in Figure 1, the typical bit rate needed for

Figure 1: Relationship between audio band-width and bit rate for mono signals

various signals can be quite high. For storage and transmission purposes, these rates quickly become prohibitive. Although disk-based storage has become cheaper and high-speed Internet connections are more commonplace, it is still difficult to stream compact disc data directly at 1.4 Mb/sec or store hundreds of uncompressed CD's on a hard disk.

The main goal of *audio* and *speech compression* is to find a more efficient digital representation of these signals. Because most signals start as simple sampled PCM signals, it is useful to use the resulting relative reduction in bit rate as a measure of efficiency. It should be pointed out that a reduction in bit rate is not always the main objective. For example, one could increase the bit rate to make the signal more robust against transmission errors. In that case, the generic term *coding* is more appropriate. In this chapter, we will use both terms interchangeably. Figure 2 shows the generic compression operation. The *encoder* takes the PCM input signal and generates the compressed *bit stream*. The bit stream is either transmitted to the *decoder* or stored for later retrieval. The decoder takes the bit stream and generates the corresponding decoded PCM signal, which is a rendering of the original input PCM signal.

In the remainder of this chapter, we will focus on reducing the bit rate of speech and audio signals while providing the best possible signal quality. At this point, it is good to point out that quality is a difficult attribute to quantify because it has many dimensions. Most of these dimensions are associated with its application, and it is important to set proper objectives when designing or choosing a particular compression algorithm. For example, for speech communications, it could be important to have a consistent performance for various input conditions such as clean speech, noisy speech, input-level variations, and so on. For compression of music signals, it could be important to have a consistent performance for various types of music or to preserve as much as possible audio bandwidth and stereo image. As will be clear later, this quality objective will be constrained by other factors such as the *delay* (the time needed to encode and decode a signal) and *complexity* (the number of arithmetic operations or memory use) of the methods used.

Speech and audio compression applications can be divided in two classes: *broadcasting* (e.g., streaming) and *communications* (e.g., Internet telephony). Each class has different requirements, as can be seen from Table 1.

There are two principal approaches to compression of digital signals: *lossless* and *lossy* compression. Lossless compression techniques take advantage of the redundancies in the numerical representation. For example, instead of using uniformly 16 bits per sample, one could use a new mapping that assigns symbols of shorter length to the most frequent values. Or if the signal values change slowly between sample values, then one could use fewer bits by encoding the differences instead. Lossless compression is a reversible operation, and both input and output signal samples of Figure 2 will be identical. Lossy compression

Table 1: Difference in Requirements for Broadcasting and Communications

Feature	Broadcasting	Communications
Characteristic	One-way transmission	Two-way transmission
Delay	Not important	Important
Encoder complexity	Not important	Important
Decoder complexity	Important	Important
Technology	Audio coding	Speech coding

techniques, on the other hand, assume that the signal has a human destination, which means that signal distortions can be introduced as long as the listener is not able to either hear them or has no serious objections. Lossy compression is not reversible, and the input and output signal samples of Figure 2 will be different. For many signals, this difference would be unacceptable; but for audio signals, one only worries about audible differences. If the differences are inaudible, then the lossy coding techniques used are often referred to as *perceptually lossless* coding techniques. But even if the differences were clearly audible, it still will be acceptable for many applications. A good example is the difference between telephone speech and natural speech, where the telephone signal is significantly limited in bandwidth (typically less than 4 kHz).

In practice, the use of lossless coding for audio and speech signals results in a limited compression efficiency, and its use is restricted to high quality applications such as the DVD audio. The compression efficiency for lossy coding can be significantly higher; consequently, perceptually lossless and lossy coding are the main approaches used in most audio and speech compression applications. Speech compression takes this approach one step further by also assuming that humans generate the source signal, which gives it certain properties that can be taken advantage of by the compression algorithms. As a result, speech compression can achieve especially high compression efficiency. Figure 3 gives a summary of the typical bit rates and applications.

Compression for Packet Networks

The compression algorithms described in this chapter are used for communication and broadcasting over wired and wireless networks. Errors that get introduced in the bit stream during transmission can introduce serious degradations in the decoded signal. In contrast to analog signals, where transmission impairments mainly introduce additional noise in the audio signal, digital signals subjected to bit stream errors result in pops, clicks, and other annoying artifacts. Especially in wireless applications, one is likely to encounter transmissions errors, and it is

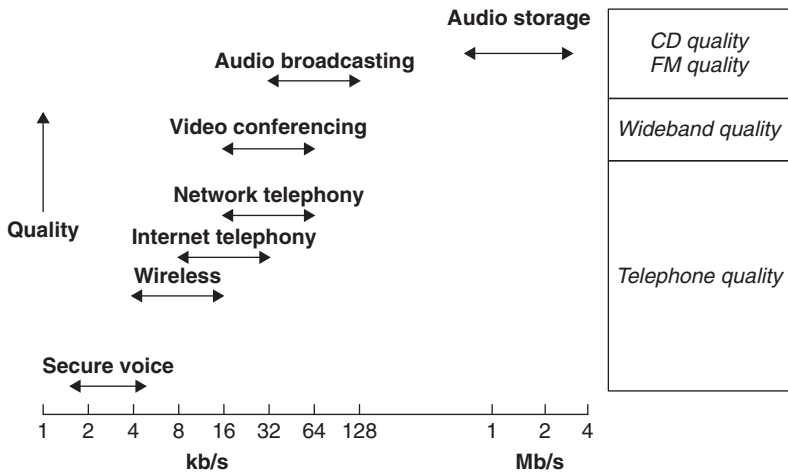

Figure 3: Typical bit rates and applications for speech and audio compression

common to add additional information for *error correction and detection*. However, even with the use of error-correction techniques, it is still possible that bit errors remain in the bit stream. The sensitivity of a decoder to random bit errors (in other words, its relative effect on the decoded signal quality) should be taken into account in such an application. For wired networks, the transmissions channels are usually good and transmission errors are unlikely. However, in packet networks (e.g., the Internet), it is possible that packets do not arrive on time. Because the decoder cannot request retransmission, this information is considered to be lost. To avoid gaps in the signal, it is necessary to fill in the missing information. This technique is referred to as *error mitigation*. Sophisticated error mitigation techniques work quite well for segments up to 40msec to 50msec but are of limited effect for longer erroneous bursts, in which case the best option is to mute the signal. It is important to realize that for applications where transmission errors can occur, the overall quality of a coder (including the use of error correction and mitigation) could be dominated by its robustness to channel impairments.

Traditional compression applications are optimized for the underlying application (e.g., a cellular system). These systems are homogeneous in the sense that all terminals and links meet certain minimum requirements in

throughput and capabilities. The Internet is a much more heterogeneous network where end points can be quite different in capabilities (e.g., low-end versus high-end, PC versus laptop, wired versus wireless), and connection throughput (dialup versus broadband). One solution would be to use *scalable* coders in which the same coding structure can be used for operation at different bit rates by simply changing some of its parameter settings. This requires a handshaking process between transmitter and receiver side to agree on the bit rate to be used. Moreover, if a throughput issue comes up somewhere in the middle of a link, it would require decoding the higher rate first and then subsequent encoding at the lower rate. The resulting *transcoding* operation introduces additional delay and a significant degradation in quality because coding distortions are compounded. A better approach is the use of *embedded* coders. In embedded coders, there is a core bit stream from which each decoder needs to decode the signal with a certain basic quality. One or more enhancement layers enhance this core layer. Each enhancement layer will increase the average bit rate and the quality of the decoded signal. The encoder generates the core layer and enhancement layers, but the decoder can decode any version of the signal as long as it contains the core layer.

This is illustrated in Figure 4. Apart from adjusting for various throughput rates, embedded coders can also be

Figure 4: Use of embedded coders in a heterogeneous network

used for temporarily alleviating congestion. If too many packets arrive at a given switch (e.g., switch 2 in Figure 4), the switch can decide to temporarily drop some enhancement packets to avoid congestion. As long as this is not done for extended periods of time and the enhancement layers have a fine granularity, this process will only introduce limited audio degradation. The embedded coding approach will alleviate packet loss problems but will not avoid them. Packet losses of the core information will still be a source of quality degradation. *Multidimensional* coders can be seen as a superset of embedded coders. In this technique, the encoder creates two or more descriptions of the signal, each of which can be decoded independently and each with a similar quality. When more descriptions are received, they are combined to produce an output of higher quality than is possible with fewer descriptions. As long as the packet losses for each description are independent of the other descriptions, by adding more descriptions it is possible to significantly reduce the probability that all descriptions suffer from a packet loss at the same time. The increased robustness is a trade-off with the need to transmit more information. In practice, it is difficult to design efficient scalable coders and multidimensional coders, and this topic is still an active area of research.

Speech and Audio Quality Assessment

The quality assessment of lossy speech and audio compression algorithms is a complicated issue. Quite often we want to assess not only the quality of the compression algorithms, but also the quality delivered by these algorithms in a typical operating scenario, which means including other aspects of the delivery chain as well, such as the quality of the network or the quality and type of playback equipment. Because the coders use perceptual techniques, it is important to use human listeners. Even in this case, care has to be taken to get reliable and reproducible results. Choice of test material, number of listeners, training of listeners, test format (e.g., ordering of playback, inclusion of original), and playback scenario (e.g., headphones versus loudspeakers) all affect the outcome of the test, and it is necessary to design the test to minimize the effect of these factors. Testing perceptually lossless coders (no audible differences when compared to original) will be different from assessing the performance of lossy coders. The latter will be complicated because trade-offs have been made in many dimensions that will produce different listener responses. Examples are the trade-off between audio bandwidth and signal quantization distortions or the stability of the reproduced stereo image. A well-designed test will try to eliminate all these biases and should produce a reproducible result.

Assessment of speech is even more involved, because it involves two-way communications and most material is context sensitive. *Mean opinion scores* (MOS), a type of testing in which panels of listeners rate the quality of short sentences on a five-point scale, are the most common. Refinements of these tests provide the original reference and the corresponding processed and compressed signal. In that case, the scores reflect a comparison that can be single-sided (degradation MOS) or two-sided

(comparison MOS). Besides speech quality, one can also test speech intelligibility, although this is usually not an issue for bit rates of 4 kbps and higher.

It should be appreciated that none of the testing methods described above can fully predict how people experience the quality in a real-world scenario, which involves talking to people whose voices they know or listening to music they like.

Tests with human subjects are expensive and time-consuming, and one would like to use objective measures that could predict subjective quality based on a comparison between original and processed version. For lossy compression, simple objective measures such as segmental *signal-to-noise ratio* (SNR) measurements are meaningless. A more effective approach is to include models that mimic our auditory system and use the resulting model output to predict subjective quality. Two standards based on such an approach have been recently recommended: (1) ITU-R BS.1387 (perceptual estimate of audio quality, or PEAQ) for the assessment of audio compression techniques and (2) ITU-T P.862 family of standards (perceptual estimate of speech quality, or PESQ) for the assessment of telephony quality speech compression techniques. Both methods rely on comparing the reference input and (decompressed) output signal. Such an approach reflects reasonably well subjective tests of high audio quality in which listeners rate the degradation relative to the reference. However, typical subjective tests for speech quality do not include direct comparisons with the reference. This means that the PESQ is unable to reflect the quality of the original signal. To address this shortcoming, ITU-T has introduced P.563, which is a single-ended measure for speech quality that does not need a reference. Although these methods have shown to be quite accurate for some scenarios, they should always be used with caution and with a clear understanding of their shortcomings.

SPEECH-CODING TECHNIQUES

Efficient digital presentation of speech signals has been a topic of research since the 1940s, but only since the early 1990s have many applications become technically and economically feasible. Digital cellular telephony has been one of the main applications for speech coding, and many digitization choices were chosen to be compatible with wired digital networks. For example, the speech signals are sampled at 8 kHz (thereby limiting the signal bandwidth to 4 kHz), single channel (mono), and 8 to 16 bits per sample. The communication application puts a constraint on the *delay* introduced by the compression operation. Not only is it difficult to have a natural two-way conversation with one-way delays exceeding 200 msec, but also it is more noticeable to hear echoes introduced, for example, by the acoustic coupling between loudspeaker and microphone (e.g., speakerphone) at either end of the communication link. For conferencing applications that involve more than two parties, each party will hear the combination signal of all other participants. Because this combining of the signals needs to be done in the PCM domain, it is necessary to decompress the signals, digitally combine them, and compress them again. The delay

introduced by compression will now be compounded, thereby reinforcing the problems mentioned above. Most compression algorithms introduce delay because they analyze the signal in blocks or frames with durations of 10 msec to 30 msec to better characterize the signal behavior and its variations.

For communication applications, it is also important to put constraints on the *complexity* of the compression operation because each end point needs both an encoder and a decoder. This is even more relevant for wireless applications where the end point is battery-powered because high complexity will reduce battery life. Complexity is defined in terms of computational load (MIPS) and memory usage (RAM and ROM). For most speech and audio-coding algorithms, there is an asymmetry in complexity, and the encoder can be several more times complex than the decoder.

Most speech coders are based on the lossy compression paradigm and take advantage of the properties of both the auditory system and the speech production mechanism. The latter can be taken advantage of by using so-called parametric coders. With these coders, the speech signal is modeled by a limited number of parameters, which are usually related to the physical speech production mechanism. The parameters are obtained from analyzing the speech signal and then quantized before transmission. The decoder will use these parameters to reconstruct a rendering of the original signal. When comparing the input and output waveforms, the resemblance can be weak, but the signals can sound quite similar. Using parametric approaches, it is feasible to achieve low bit rates (2 kbs to 4 kbs) with a reasonable quality. The quality is limited by the accuracy of its model. This is illustrated in Figure 5. To avoid this limit in quality, a more common approach is to use waveform-approximating coders. These coders maintain the waveform of the original signal as much as possible while taking advantage of the properties of both the speech production and auditory mechanisms. The resulting quality is better at the expense of higher bit rates; at lower bit rates, the quality of a waveform coder will be less than a parametric coder operating at the same low rate.

Speech produced by humans has certain properties that can be taken advantage of for compression. It has limited energy above 8 kHz, and it has a limited dynamic range. This allows sampling with frequencies between 8 kHz and 16 kHz, and PCM quantization with 1216 bits/

Figure 5: Quality versus bit rate curves for waveform and parametric coders

sample. Using nonuniform quantization (i.e., the quantizer step sizes are small for small input values and large for large input values), it is possible to quantize telephony speech with 8 bits per sample. Figure 6 shows a waveform and its corresponding spectrogram. Looking at this figure, we see that the envelope of the amplitudes change slowly as a function of time. The spectrogram shows that certain frequencies are stronger than others. These emphasized frequencies, called *formants*, are caused by resonant frequencies in the human vocal tract in response to the glottal excitation signal. The resonant frequencies are moved by changing the shape of the mouth cavity over time. The relative position of these formants defines the sounds and vowels that we perceive. We can also see a more harmonic component, which results from the periodic excitation by the vocal cords. The estimate of the fundamental frequency of this harmonic excitation is referred to as the *pitch* and varies between 100 and 250 Hz for males and 200 to 400 Hz for females.

All of these features are produced by the human articulatory system, which changes slowly in time because it is a biological system driven by slowly moving muscles. As a result, the formants can be effectively represented by a slowly varying adaptive digital filter, the *linear* or *short-term prediction* filter. With only ten predictor coefficients updated once every 20 msec, it is possible to accurately reproduce the evolution of speech formants.

Figure 7 shows a short segment of a speech signal and the corresponding signal after filtering it with this adaptive linear prediction filter. This figure shows another generic characteristic of speech signals: Some segments are more noiselike or *unvoiced* and others are more periodic or *voiced*. Voiced segments have distinct pitch, whereas the pitch of unvoiced segments is undefined. The filtered signal is called the *residual* signal. Because this signal has a reduced dynamic range and less variance, it can be quantized with fewer bits per sample. Although it is possible to derive the prediction coefficients without explicitly

Figure 6: Time waveform of the utterance “Why were you away a year, Roy?” spoken by a female speaker (top) and corresponding spectrogram (bottom). The spectrogram shows the power spectrum as a function of time, where the gray level indicates the power levels from low (white) to high (black)

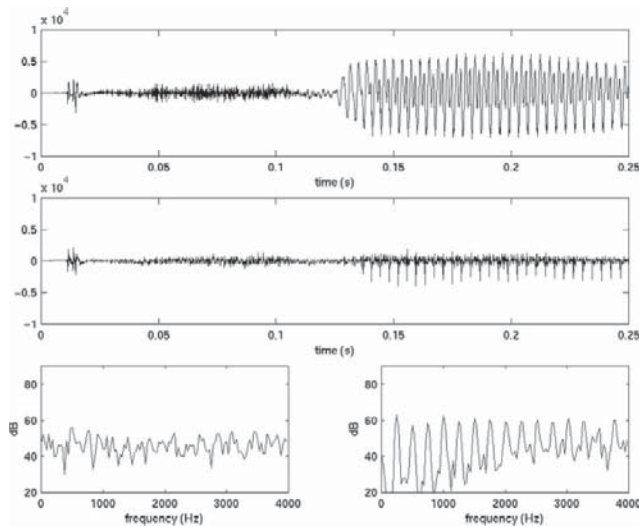

Figure 7: Time waveform (top), corresponding residual signal (middle), and spectra of the residual signal (bottom) for the first part of the sentence (left) and second part of the sentence (right)

transmitting them (*backward adaptation*), it is more common (especially for lower-rate coders) to quantize and transmit the predictor coefficients explicitly (*forward adaptation*). Numerous methods are available, and the most effective methods require only 1500 to 2000 bits/sec for transmitting ten coefficients every 10 to 20 msec. Predictor efficiency can be further improved by recognizing that speech signals contain significant periodic components for voiced sounds (e.g., vowels). A *long-term* or *pitch predictor* is able to predict the periodic component, resulting in an even more noiselike residual signal. The long-term predictor consists of variable delay line with a few filter coefficients. The delay and coefficients are updated once every 5 msec to 10 msec. The most typical configuration is *forward adaptive*, which means that approximately 1500 to 2000 bits per second are needed for transmitting the long-term predictor parameters. Figure 8 shows the signals after short- and long-term prediction, respectively.

The signal shown at the bottom of Figure 8 resembles a noiselike signal with a reduced correlation and reduced dynamic range. As a result, it can be quantized more efficiently. At this point, we have all of the components needed for a linear predictive-based coder. A block diagram is

Figure 8: Time waveform (top), short-term residual signal (middle), and long-term residual signal (bottom)

shown in Figure 9. The signal is filtered with the *short-term filter*, $A(z)$, and *long-term filter*, $P(z)$, and the remaining residual signal is quantized. The predictor parameters and quantized residual signal are transmitted or stored. After decoding the quantized residual signal, the decoder filters this signal through the inverse long-term and short-term prediction filters. Note that, without quantization of the residual signal, the decoder can exactly reproduce the original signal. For quantization of the residual signal, many techniques exist. The simplest quantizers are scalar uniform or nonuniform PCM quantizers. For acceptable results, at least 4 to 5 bits per sample are needed. Even refinements such as adaptive quantization, in which the step sizes are adjusted over time, will not reduce the number of bits per sample significantly.

More efficient quantization can be obtained through the use of *vector quantization* (VQ), in which multiple samples are quantized simultaneously. This is achieved by having a number of possible representative sample sets or *codebook*. The quantization is achieved by selecting the codebook entry (each entry containing multiple samples) that is the best representation of the signal to be quantized. The codebook index corresponding to this

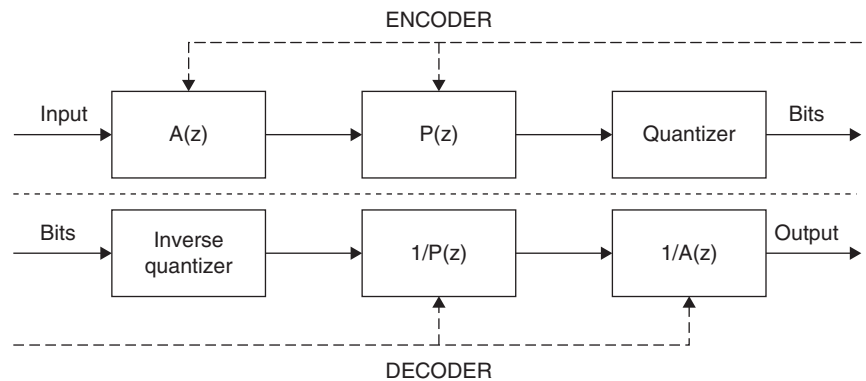

Figure 9: Block diagram of a linear predictive-based coder with short-term and long-term prediction

entry is transmitted, and the decoder, which has a similar codebook, uses this index to look up the corresponding values. Although the lowest quantization rate for scalar quantization is one bit per sample, VQ allows fractional bit rates. For example, quantizing two samples simultaneously using a one-bit codebook will result in 0.5 bits per sample. More typical values are a ten-bit codebook with codebook vectors of dimension forty, resulting in 0.25 bits/sample. The objective of both scalar and vector quantization is to find the quantized value that is the closest to the original nonquantized input. In the block diagram of Figure 9, one can argue that the overall goal is not to find the best quantized residual values but the best quantized speech signal. Especially for coarse quantization (few bits per sample), this becomes an important distinction. A powerful technique used in speech coding is *analysis by synthesis* in which the effect of quantization is determined by examining the effect on the decoded output. This is accomplished by operating the diagram of Figure 9 in the configuration shown in Figure 10.

In this figure, the encoder of Figure 9 is enhanced with a local decoder. In most practical coders, the predictors are still computed as usual. The quantization of the residual signal is done in an analysis-by-synthesis fashion. If we assume that we use a codebook, then the essence of this approach requires that for each codebook vector we perform local decoding and compare the resulting prototype output with the original input signal. The codebook vector that gives the best approximation is selected. Note that with this paradigm we are indirectly creating a quantized residual signal, and this signal is often referred to as *excitation* signal. Instead of directly comparing the original input signal, and the quantized and decoded rendering of this signal, an error-weighting filter is introduced that better reflects the way our auditory system perceives distortions. Note that this weighting is much simpler than the complex auditory models used in audio coding. The block diagram of Figure 10 forms the basis for a family of coders generically referred to as *code-excited linear predictive* (CELP) coders. Most modern standards are based on this principle. A large amount of research has been done on efficient codebook structures that not only give the best performance but also are manageable in terms of search and memory requirements. A commonly used structure is the so-called algebraic codebook, which consists of a few nonzero pulses with deterministic positions.

For any speech coder, several techniques can be used to further improve its performance. Some of these techniques can be done independently of the coder, although in practice it makes sense to take advantage of the parameters already computed by the coder. Preprocessing

Figure 10: Analysis-by-synthesis encoder with error weighting

techniques that are useful are *gain control* and *noise suppression*. The latter can be quite sophisticated but highly effective, especially for the lower-rate speech coders, which typically do not handle background noise well. A widely used form of postprocessing is *postfiltering*. In this process, the decoded speech signal is slightly distorted in a way that suppresses the coding noise and enhances the signal. If done with care, it can clean up the signal, resulting in a perceived quality improvement.

Another technique that has found some popularity is taking advantage of the fact that conversational speech comes in bursts because talkers speak at alternating times. Sometimes, there can be large pauses between words. This can be exploited by only transmitting when active speech is present. When speech is not active, no signal is transmitted. Because, on average, people speak one-half of the time, this technique has the potential to reduce the bit rate by half. To make this *discontinuous transmission* approach work, a *voice activity detector* (VAD) is needed. For speech without background noise, this approach can work quite well. When background noise is present (e.g., car sounds), it is more difficult to get reliable decisions from the VAD. Moreover, when no talker is active and no signal is transmitted, the receiver side needs to substitute a replacement signal. This is referred to as *comfort noise*. For high levels of background noise, it is difficult to have this comfort noise match its characteristics. Hence, more sophisticated systems transmit low-rate information about the background noise, such as energy and spectral characteristics, at average rates of 1 kbs to 2 kbs. The resulting system is a *variable bit rate* (VBR) system. This concept could be further extended to coding the speech on a frame-by-frame basis with a different bit rate depending on the characteristics of the signal, or it could be controlled by the overall communication system. Variable bit rate systems are able to produce similar quality as fixed bit rate systems but at a lower average bit rate. However, the system issues become more complicated because of the need to track all these rate changes throughout the whole communication chain.

Speech-Coding Standards

For communications purposes, it is important to establish standards to guarantee interoperability between equipment from different vendors or between telecommunication services between different geographic areas. Telecommunication standards are set by different standard bodies, which typically govern different fields of use. The International Telecommunications Union (ITU-T) establishes worldwide telephony and communications standards, while regional standards bodies such as the European Telecommunications Standards Institute (ETSI), and Telecommunications Industry Association define standards that are more regional in character (e.g., wireless standards), although this distinction is disappearing because of globalization. It is also common to have the same coding standard adopted by more than one standard body. For example, the ITU-T G722.2 wideband coder and the ETSI/3GPP AMR-WB coder are referring to the same standard. Table 2 summarizes the most relevant ITU-T and ETSI speech-coding standards.

Table 2: Summary of Relevant ITU-T and ETSI Narrowband (8 kHz Sampling Rate) Speech-Coding Standards

Coder	Algorithm	Rate (kbs)	Frame size	Complexity	Quality
G.711	μ -law/A-law	64	1	*	*****
G.726	ADPCM	16, 24, 32, 40	1	**	**_*****
G.727	ADPCM	16, 24, 32, 40	1	**	**_*****
G.728	LD-CELP	16	5	*****	*****
G.729	CS-ACELP	8	80	****	****
G.723.1	MP-MLQ	6.3	240	****	***
	ACELP	5.3	240	****	**
AMR-NB	ACELP	4.75–12.2	160	****	**_*****

Quality and complexity are indicated by asterisks; with * meaning low and ***** meaning high.

Table 3: ITU-T and ETSI Wideband and Superwideband Speech Coders

Coder	Algorithm	Sample rate (kHz)	Rate (kbs)	Frame size	Complexity	Quality
G.722	ADPCM	16	48, 56, 64	1	*	***_****
G.722.1	Transform	16	24, 32	320	***	***_****
G.722.1 Annex C	Transform	32	24, 32, 48	320	***	****
G.722.2/AMR-WB	CELP	16	6.6–23.85	320	****	**_*****

Quality and complexity are indicated by asterisks; with * meaning low and ***** meaning high.

Note that several other speech-coding standards exist, specifically for military and government applications. Typically, the bit rates are significantly lower (less than 4kbs), and the resulting quality is lower than typical civilian cellular communications standards.

Besides the main standard there are many extensions or, in ITU-T terms, annexes. G.729 Annex A, for example, is a low-complexity version of G.729 that generates bit-compatible output. It requires only half the complexity at the expense of a minor degradation in speech quality. Other annexes of G.729 define a low-rate and high bit rate versions and integration with VAD.

Most of the discussion has focused on coders for 8-kHz sampling rate, which limits the audio bandwidth to 4kHz. With the availability of new end points, it is now more feasible to provide higher quality output, specifically increased audio bandwidths. A commonly used sampling rate is 16kHz, which supports audio bandwidths up to 8kHz. More recently, some standards have been established for superwide band coders that support audio bandwidths of 14kHz using a 32-kHz sampling rate. Table 3 summarizes several ITU-T and ETSI standards that have been defined for encoding these so-called wide-band signals.

Most of these ITU-T standards not only have a detailed technical description of their underlying algorithms but also are accompanied by reference source code and test vectors. The source code is provided as floating-point C code, fixed-point C code, or both. Fixed-point code

reflects implementation on signal processor and VLSI chips, which are typically used in most portable devices.

It is worthwhile mentioning that although standards make the technology readily available, they are not license free. In most cases, proper royalty agreements have been obtained before one can use the coder in a commercial application. Although G.729 is one of the more commonly used coders used in *voice over Internet protocol* (VoIP) applications, the need to pay royalties has affected its deployment. This has created the opportunity for open-source royalty-free coders such as the iLBC coder, which has been adopted by IETF as a standard. This coder has as an additional advantage that it does not require information from past frames, which reduces its coding efficiency but makes it extremely robust against packet losses.

In general, all the above speech-coding algorithms are highly effective for the compression of speech and speechlike signals (noisy speech), but in general not the best for music signals. This is to a large extent because of the speech-modeling components incorporated in these coders. As will be discussed in the next chapter, audio coders do not make assumptions about the underlying production model and hence work in general much better for music and other signals. However, at the lower rates and for speech signals specifically, these coders tend to produce coding artifacts. As a result, there is a transition area where neither coder paradigm is optimal. Recent advances in the field have produced coders that try to fill

that void by offering hybrid architectures that use both speech- and audio-coding paradigms and adaptively combine these elements as a function of signal content. The AMR-WB+ coder standardized by ETSI is one example, and other proposals can be found in the literature. However, to declare these coders as truly universal coders might be a far stretch, and it is unlikely that there ever will be a single truly universal coder that covers all possible application scenarios and constraints.

AUDIO-CODING TECHNIQUES

The most common high-quality audio distribution format is based on the compact disc format introduced in the early 1980s. The signal is encoded using PCM with 16 bits/sample at a 44.1 kHz sampling rate. For stereo signals, this means a data rate of $44,100 \times 16 \times 2 = 1.41$ Mbs. More recent formats such as the DVD audio support as many as 24-bit samples in multichannel format (e.g., 5.1) and sampling rates as much as 192 kHz, resulting in even higher data rates. For most practical purposes, these signals will be used as the digitized source signals. For Internet streaming and computer storage applications, it is necessary to reduce these rates significantly and bring them in the 32 kbs to 128 kbs range. As discussed earlier, this can be accomplished by the use of perceptual lossless coders, which take advantage of the limitations of our auditory system. For CD quality, it is possible to make signals sound perceptually indistinguishable from the original at 64 kbs per channel (128 kbs for stereo). At lower rates, we lose some of the information, but if done by proper combinations of bandwidth reduction, reduced dynamic range, and mono instead of stereo, the resulting signal will still be acceptable for many applications.

Perceptually lossy and lossless compression use two main techniques. First, we have the *irrelevancy* removal, which removes parts of the signal that we cannot hear. The second technique, *redundancy* removal, finds the most compact signal representation. Irrelevancy removal exploits the properties of the human auditory system.

The human auditory system is a highly sophisticated system with tremendous capabilities. It acts as a converter of acoustic waves to auditory nerve firings while performing a spectral analysis as part of this process. The auditory system has been shown to have masking properties. *Masking* describes the process in which one signal becomes inaudible in the presence of another signal. In other words, under certain circumstances it is possible to make quantization noise inaudible while the decoded audio signal is present.

Masking can happen both in time and in frequency. Understanding the principles of masking has taken many decades of research using both physiological and physical measurements. Masking data are obtained through psycho-acoustical studies in which subjects are exposed to test signals and asked about their ability to detect changes (e.g., increases in frequency, audibility, etc). Most of the understanding of masking is based on simple tones and noise. Because complex signals can be viewed as a composite of time-varying tones, a common approach has been to derive the masked threshold by analyzing the signal tone by tone in specific frequency bands that are common to the human auditory system. These bands are called *critical bands* and are spaced nonuniformly with increasing bandwidth for higher frequencies. In each critical band, the signal and its corresponding masking function are calculated, and the masked threshold is derived as a superposition over the complete frequency band. Note that the actual procedure is much more complicated, taking into account several interactions and signal characteristics (e.g., if the signal is noiselike or tone-like). Figure 11 gives an example of the power spectrum of a signal and its corresponding masked threshold. In this figure, as long as the quantization noise remains below the solid stepped line, it will be inaudible.

In general, the model that is used to derive the masked thresholds is referred to as the *psychoacoustic* or *perceptual* model. Building a good perceptual model and matching it properly to a given coder structure is a complex task. Note also that for a given coder structure (or coder standard such as MPEG-1 layer 3), it is possible to

Figure 11: Example of signal frequency power spectrum and its corresponding masked threshold (solid stepped line)

improve the perceptual model while still being compliant to the standard. This also explains the differences in various encoders that all support the same standard. To achieve redundancy removal, and at the same time take advantage of the frequency domain masking properties, it is beneficial to perform a spectral decomposition of the signal by means of a filter bank or transform. Most modern audio coders are based on some form of lapped transform that not only provides computational efficiency but also allows perfect reconstruction. In other words, the process of transform and its inverse will produce the original (although delayed) version of the original time signal. The transform sizes and overlaps will be chosen in such a way that the signal is critically sampled (i.e., the number of frequency components is the same as the number of time samples). The size of the transform will determine the spectral resolution. A larger transform will provide a better spectral resolution at the expense of a decreased time resolution. A common solution is to make the transform size adapt to the signal. For stationary signals, a large transform size is chosen; for nonstationary signals or onsets, a smaller transform size is chosen. Typically, sizes vary from 256 to 2048 samples for sampling rates in the 20 kHz to 40 kHz range. This process is called *window switching*, and care is taken to make sure that the whole process is invertible. A commonly used transform is the *modified discrete cosine transform* (MDCT). It uses a transform of length $2M$ samples, which advances M samples between adjacent transforms. It is critically sampled, and only M coefficients are generated for each $2M$ set of input samples. Computationally efficient implementations have contributed to the widespread use of the MDCT in many audio-coding standards.

Figure 12 shows a generic block diagram of an audio encoder that incorporates the filter bank and the perceptual model. The resulting spectral components (MDCT coefficients) are quantized in such a way that the resulting quantization noise is inaudible. This is accomplished by using the masking level obtained from the *perceptual model*. The amount of noise is controlled by the resolution

of the quantizer. By choosing a different quantizer step size, the amount of noise can be quantized. Typically, the same quantizer is used for a set of coefficients, and the corresponding step size for that set is transmitted to the decoder. Note that because of quantization, the decoded signal will be different from the original (i.e., lossy coding). To accomplish perceptually lossless coding, we need to make sure that the quantization noise remains below the masked threshold. The redundancy removal is accomplished by encoding the quantizer indices with lossless coding techniques (e.g., Huffman coding). To avoid confusion, it should be clear that this is a lossless coding technique on quantizer indices, hence the overall operation is still a lossy coding operation. The resulting bit rate will be variable and signal-dependent. In many implementations, an iterative procedure is used to find the optimum quantizer step sizes that result in coding noise below the masked threshold; this will result in the lowest possible bit rate.

The decoder operation performs the operation in reverse without the need for a perceptual model. A generic block diagram of an audio decoder is shown in Figure 13. After reconstructing the coefficients, the signal is transformed back to the time domain ready for playback.

The block diagrams of Figures 12 and 13 are the principle for coding a single audio channel. For encoding multiple channels (N channels), we could in principle use N of these encoder-decoder pairs. However, in practice we would like to take advantage of the possible correlations that exist between the various channels. Also, for transparent coding, we should take into account that masking levels will differ for signals that are spatial in nature. Some distortions that are inaudible in each individual channel will become audible when listening to its multichannel version (e.g., in stereo).

Most state-of-the-art audio coders will produce a variable bit rate. In most communication scenarios, a fixed bit rate is more desirable. This is accomplished by a buffering scheme that interacts with the coder quantization decisions. Designing buffering schemes that minimize

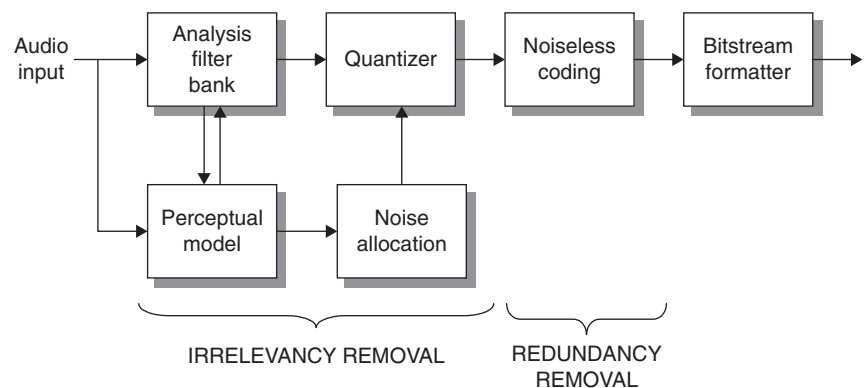

Figure 12: Block diagram of generic audio encoder

Figure 13: Block diagram of generic audio decoder

buffer size (and its corresponding delay) and minimize impact on audio quality turns out to be a challenge, and various solutions exist, each with its own advantages and disadvantages.

Enhanced Audio-Coding Techniques

The audio-coding techniques discussed in the previous section achieve significant compression efficiency and can produce stereo CD quality audio at bit rates as low as 80 kbs to 128 kbs. At the same time, there is a need for acceptable quality stereo coding of audio at bit rates as low as 24 kbs. Two signal dimensions that have recently been successfully explored and resulted in additional standardization activities are efficient coding of high-frequency information and the encoding of spatial information as typically captured in multichannel signals (e.g., stereo and surround). It should be noted that these dimensions are now explored in a similar context as lossy compression where certain a priori decisions are made that will result in certain nonreversible signal degradation. However, these trade-offs when done properly will produce quite acceptable audio quality at lower bit rates and will enable additional applications. Because this approach can be viewed as an extension to existing lossy and lossless audio coders, it is useful to incorporate them as shown in Figure 14.

The input audio signal is analyzed and possibly modified by the extension analysis module. The extension parameters are typically transmitted as part of the core bit stream. The original or modified audio signal is encoded using the core audio encoder with appropriate settings. At the decoder side, the core audio bit stream is decoded as usual, and the extension synthesis module uses this decoded audio signal together with the transmitted extension bits to reconstruct the final audio output. One advantage of this approach is that these extensions can be added in a backward-compatible manner, which is critically important for coders that are widely used. The compatibility is such that legacy decoders can decode the core bit stream but obviously cannot process the transmitted extension information. In that case, the resulting signal could be severely limited in audio bandwidth and be mono instead of stereo.

As mentioned, one dimension to explore is audio bandwidth. To encode a signal with its full audio bandwidth requires a significant number of bits. At the same time, most listeners will have difficulty hearing frequencies beyond 11 kHz to 15 kHz, somewhat as a function of age. Some encoders will limit the audio bandwidth a priori; but, depending on the listener, this trade-off could be unacceptable. A better approach is to recognize that it is good to have high frequency content, but that an approximation of this part of the signal is adequate to most

people and for most signals. Such approach is enabled by a technique referred to as *bandwidth extension*. The basic principle is to encode the original audio signal up to a certain predetermined bandwidth. The higher frequency content is not explicitly transmitted but approximated from the transmitted low-frequency audio signal. Such an approach is possible because most signals show some correlation between low- and high-frequency contents. Moreover, this approximation is enhanced by analyzing the original high-frequency content and deriving guidance parameters that can help with reconstruction of the missing high frequencies at the decoder side. These guidance parameters are transmitted as a separate (low-rate) bit stream or added to the core bit stream. A widely used bandwidth extension technique is *spectral band replication* (SBR) first introduced as a commercial enhancement as part of mp3PRO and aacPlus, and later standardized in MPEG-4. SBR approximates the higher-frequency information by a transposed version of the lower-frequency band, and the guidance parameters provide information about the details of this transposition as well as the energy envelope of the nontransmitted higher frequencies. If the transmitted lower-band cutoff frequency is chosen to be not too low (e.g., above 9 kHz), the resulting audio quality will be quite good at bit rates as low as 48 kbs for stereo. It is possible to lower this cutoff frequency; but, depending on signal contents, distortions will be audible, although in most cases they will be not objectionable. The bit rate for the guidance information is typically a few kbs.

As mentioned, the other dimension to explore is spatial information existing in stereo and multichannel audio. To encode a multichannel signal requires a significant number of bits, especially for surround signals (e.g., 5.1). Although modern coders take advantage of the correlation between the various channels, at lower bit rates it is necessary to reduce the number of channels and transmit multichannel as stereo or stereo as mono. Similar to bandwidth extension, it was recognized that it is important to have spatial information but that it is possible to approximate this signal feature. The spatial content is not explicitly transmitted, but spatial features are extracted from the original signal and transmitted as a separate (low-rate) bit stream or added to the core bit stream. This technique is referred to as *spatial audio coding*. The signal to be encoded with the core audio coder is a modified version of the original signal. In its extreme case, this modified signal is a mono version of the input signal obtained by downmixing the input signal using a linear combination of the various signals. The mono signal is using conventional audio-coding techniques, or it could be encoded using the bandwidth extension techniques described above. The spatial features of the input signal are analyzed and encoded separately. The decoder first reconstructs the core audio signal, and the extension

Figure 14: Generic block diagram for adding extensions

synthesis reinserts the spatial features to create the multichannel output signal. The spatial features contain frequency-dependent level and delay information between the various channels and can be encoded with a 5 kbs to 20 kbs. For a stereo signal, the savings are substantial, but the best savings are obtained when encoding surround sound signals (e.g., the 5.1 format). Although the results using a downmixed mono signal are quite impressive, for backward-compatibility reasons it is beneficial to use a downmixed stereo signal. In that case, legacy receivers will continue to receive the same stereo content, while enhanced receivers will be able to render the surround sound signal. The methods used are quite robust and work with both automatic and manual downmixes. One version of this technology has been incorporated as a proprietary enhancement to mp3 as MPEG-3 surround. A more advanced and flexible version has been standardized as an amendment to MPEG-4 audio.

Audio-Coding Standards

Two types of standards exist. The first type is based on a sanctioning by a standard organization (e.g., ISO and its MPEG standards). The second type is based on a proliferated proprietary de facto standard (e.g., Windows Media Player, RealPlayer, Dolby AC-3, etc.). In both cases, proper licensing is needed to use these standards in commercial applications. The MPEG coding standards are widely used for audio and video. The well-known mp3 standard is actually MPEG-1, layer 3. Table 4 summarizes the MPEG audio standards.

The MPEG standards are defined in a different way than most ITU-T speech-coding standards. They consist of a normative part that defines the bit stream syntax and the decoder description (sometimes accompanied by reference C code). As a result, anyone should be able to implement proper decoders. The encoder is described in the informative part and just describes the algorithmic concepts and operating modes. However, to build good encoders, it is necessary to understand the algorithms, and the standard document will not provide details on how to build a good encoder. As a result, standard compliant encoders can be quite different in performance. However, sometimes adoption of certain standards such as MPEG audio by other standard organizations (e.g., 3GPP) that require more normative definitions of the encoders has helped proliferate good reference encoders.

Besides the coders based on the traditional coding paradigm described above, other paradigms exist as well. These alternative paradigms play a role in very low rate coding. Two paradigms that have become part of the MPEG-4 standards are structured audio and parametric audio coding. *Structured audio* consists of a set of tools that can be used to generate music in a way similar to a music synthesizer. It also contains a structured way of describing musical scores and its subsequent conversion to sound using synthesizers. A structured audio bit stream describes how to build the synthesizers and provides the musical score and information on how to play this on the synthesizer. The resulting description can be quite compact and low bit rate (only several kbs). The resulting audio signal can be especially high quality, and because

Table 4: Overview of Various MPEG Audio Standards

Standard	Year	Rates for transparency (stereo, 44-kHz sampling)	Channels	Comments
MPEG-1 audio, layer 1	1992	384 kbs	Mono, stereo	48-, 44.1-, 32-kHz sampling rates
MPEG-1, layer 2	1992	192–256 kbs	Mono, stereo	48-, 44.1-, 32-kHz sampling rates
MPEG-1, layer 3	1992	128–160 kbs	Mono, stereo	48-, 44.1-, 32-kHz sampling rates
MPEG-2, layers 1–3	1994	See MPEG-1 rates	Mono, stereo, and 1 backward-compatible 5.1 multichannel	MPEG-1 + enhancements; supports lower sampling rates
MPEG-2, AAC	1997	96–128 kbs	Mono, stereo, multichannel up to 48 channels	Not compatible with MPEG-1, -2; supports 96-kHz sampling
MPEG-4 version 1	1998	96–128 kbs	Mono, stereo, multichannel	Supports various coding tools
MPEG-4 version 2	1999	96–128 kbs	Mono, stereo, multichannel	Supports error robustness tools
MPEG-4 audio 1 amendment	2003	48–96 kbs	Mono, stereo, multichannel	Bandwidth extension
MPEG-4 spatial audio coding	2006	64–128 kbs	Stereo and multichannel	

many modern music productions use synthesizers extensively, it can be especially close to some originals. *Parametric audio coding* uses similar ideas as those used in speech compression by modeling some of the production mechanisms of the music sounds. Although it will work well for some sounds, it is difficult to make this technique work consistently for a large variety of input signals.

APPLICATIONS

Two popular Internet applications of speech and audio compression are telephony (e.g., Vo IP) and music downloading and streaming. The IP data network is used to transport digitized (and compressed) audio signals. However, several layers of protocol need to be added to match the application: for example, information about the order of the information, indication of which packets have been received, and so on. To provide a complete phone service, it is necessary to support numbering schemes, billing and call setup protocols, and servers that can act as intermediaries between end points.

Another challenge in transmitting real-time sensitive data over a packet data network is the fact that the Internet is a best effort network. This means that one cannot guarantee the on-time arrival of the audio data; this may result in interruptions in the audio or it may introduce unacceptable delays. In other words, *quality of service* (QoS) cannot be guaranteed for real-time communications. Many recent efforts have focused on improving this situation. For example, new protocols support differentiation of the packets in terms of being real-time critical or not, and improved routing schemes reducing the overhead needed for traffic-flow management. To give real-time sensitive data a better guarantee of arrival, it is necessary to prioritize these packets. Keep in mind that prioritization can only work if other packets can get a lower priority and if routers can handle these priority requests. To reduce the impact of variations in arrival times, it is common to apply buffering of the packets. For one-way communications such as streaming, that is a manageable solution; for real-time applications such as VoIP, this buffering can only be done with a limited buffer size before conversational speech becomes impaired.

There are two popular ways of distributing music over the Internet. *Downloading* is a copy operation from a server that contains the original or compressed version of the material. The downloading will typically use the TCP/IP protocol, and one has to wait until all of the material has been downloaded before being able to play the music. Once downloaded, the same material can be played repeatedly. The other common way of music distribution is *streaming*, which is similar to radio broadcasting. The material is transmitted to the end user, but the signal is played out almost instantaneously without local storage. Similar to the VoIP scenario, it is necessary to buffer the packets to compensate for late arrival. Because this is a broadcast or one-way communication scenario, the amount of buffering can be large (a few to 30 seconds). Although, in principle, the buffers could be made even larger, it will create large delays before a player produces an audible signal. From a user interface perspective, this is undesirable. Hence, sophisticated

buffer control has been developed to make sure that a continuous throughput is maintained while a relatively small buffer is maintained. Some streaming services accomplish this by reducing the coder rate temporarily if the average available connection rate cannot support the initial streaming rate.

The compression techniques used are typically based on audio-coding algorithms because most material that is being streamed will be music. For lower rates, it is possible that speech-coding algorithms are used instead. A commonly used format is the mp3 (MPEG-1 layer 3) format that runs at bit rates varying from 64kbs to 128kbs. For streaming applications, it is possible to use proprietary coders, as long as the decoders are available as downloads. However, most content providers will only support one or two formats; as a result, a couple of proprietary standards have become de facto standards. Examples are Microsoft's Windows Media Player and Real Networks' RealPlayer. These proprietary coders have a reasonable quality versus bit-rate performance while trading off other parameters such as delay, complexity, and audio bandwidth. As should be clear from the previous sections, the best quality is obtained at higher bit rates (e.g., 96kbs to 128kbs); at lower rates (e.g., 24kbs to 64kbs), trade-offs will be made in reducing the audio bandwidth, or even switching to mono. However, use of advanced audio techniques such as bandwidth extension and spatial audio coding help to reduce the bit rates without compromising the audio quality too much. Note also that even at the same bit rate and using the same format, differences in quality could exist because of the quality of the source material and the encoder used. For most streaming applications, it is important that a variety of rates can be accommodated to support the various connection speeds. It is also important that the decoder has a relative low complexity to allow it to run on the host processor. With the advances in computing speed, this has become less of an issue. However, if these formats are used for downloading in portable players, complexity becomes an issue because it is related to battery life and cost.

CONCLUSION

This chapter has explained the basics of speech and audio coding and their applications to Internet telephony and Internet streaming. It should be clear that, especially for the lower bit rates, there is no single coder that is good for all applications and that careful tailoring toward the application is important. Speech and audio coding is a mature field with many available solutions. Based on our current knowledge, and the various constraints that exist, it is expected that future developments in this field will focus less on compression efficiency and more on application-specific issues such as scalability, error robustness, delay, and complexity. Specifically, solutions that use the same algorithmic architecture to support a large range of applications, bit rates, signals, and quality levels are of interest. Another area of interest is coders that can be used to provide both lossless and lossy solutions using a similar algorithmic framework.

GLOSSARY

Audio compression: The process of reducing the amount of digital information to describe audio and speech signals while maintaining the audio quality as much as possible.

Code excited linear prediction (CELP): A technique based on analysis by synthesis and widely used in speech compression standards.

Digitization: The process of creating a digital version of an analog signal by sampling and quantization.

Error mitigation: The process of reducing the perceivable impact of transmission errors of a compressed audio signal.

International Telecommunications Union (ITU): The organization that sets standards for global communications.

Linear prediction: A commonly used technique in speech compression to remove redundancies in a speech signal.

Lossless compression: An audio compression technique that uses redundancies of the signal to achieve compression. The (decompressed) output signal will be identical to the input signal.

Lossy compression: An audio compression technique that uses redundancies and irrelevancies of the signal as well as acceptable quality compromises to achieve compression. The (decompressed) output signal will be different and sound different compared to the input signal.

Motion Picture Experts Group (MPEG): An organizational part of the International Organization for Standardization that sets worldwide standards for media compression.

Perceptually lossless compression: A particular subset of lossy compression techniques in which the differences between input and (decompressed) output signals are measurable but not audible.

Quality of service (QoS): A term commonly used in the context of Internet communications and broadcasting to describe consistency in delivering a particular signal quality.

Quantization: The process of converting an analog value into a discrete digital value.

Sampling frequency: The rate at which analog signal samples are digitized. The value of the sampling frequency will be twice the highest possible frequency that can be contained in the signal.

Streaming: The process of delivering audio signals over a packet network for continued broadcasting.

Transcoding: The process of converting from one compressed format to another by decoding and encoding.

If the coders used are lossy coders, the transcoding process typically introduces additional degradation.

INTRODUCTION

Multimedia streaming enables users to access multimedia data in real time by pipelining data delivery and playback. This pipelining allows the playback of a video or an audio file to start promptly, as opposed to requiring the user to wait for the whole file to download. Streaming offers other important advantages as well. In particular, it has the capability of conveying live events, such as news and sports games. Moreover, it can alleviate copyright concerns because the streamed files are not written to the user's hard disk. The data arrive piece by piece, and each piece is decoded, played back, and then discarded.

Streaming is employed by various multimedia networking applications: *video on demand* (VOD), *live streaming*, and *interactive real time*. VOD delivers stored multimedia content to users and allows them to apply VCR-like operations such as pause, resume, fast forward, and fast rewind. By contrast, live streaming offers live multimedia content. Naturally, users cannot fast forward through multimedia data with this application. Other interactive operations, however, such as pause and rewind, may be applied with local storage of appropriate portions of the data. On the other hand, interactive real-time applications such as Internet telephony and videoconferencing, allow users to communicate with each other in real time.

Multimedia streaming has grown dramatically in popularity over the Internet. Currently, streaming is widely used by television and radio stations, news companies, e-tailers, entertainment companies, and many others. "State of the Consumer Streaming Market," a December 2005 report by comScore Networks, demonstrates the broad reach of streaming, showing that more than 100 million U.S. users—approximately 60 percent of the U.S. online population—access online digital media by streaming and downloading in a month. Moreover, in August that year, nearly two-thirds of U.S. Internet users had streamed audio or video through a portal, and almost 50 percent had done so from an entertainment Web site. In addition, more than 17 percent of these users streamed content from music Web sites, and 15 percent had streamed from retail Web sites. (The report does not provide statistics for streaming usage in other countries.)

This chapter discusses the basics of multimedia streaming over the Internet. First, it illustrates how streaming works then discusses the standardized network protocols used for streaming and their coordination in a streaming session. The chapter proceeds by discussing the main challenges in streaming multimedia over the Internet. It also surveys the main approaches and techniques that can be used to address these challenges. Finally, the design of streaming servers is discussed, covering the main aspects of admission control, resource sharing, request scheduling, and storage subsystem management.

HOW STREAMING WORKS: AN OVERVIEW

An Internet user can request the streaming of a stored multimedia file by clicking on its hyperlink, which points to a description file rather than the actual multimedia file. The description file contains the URL of the multimedia file and its type of encoding. For example, the description file may have the following line:

```
rtsp://www.univserv.edu/~user/AlienSong.mov
```

The URL descriptor "rtsp://" identifies the requested media stream. When the user clicks on the hyperlink, the Web browser retrieves and opens the description file and then launches the appropriate *media player* such as Real Player, Windows Media Player, or QuickTime. Subsequently, the media player establishes a connection with the corresponding *streaming server*, which decomposes the file into packets and sends them as a stream to the client's media player. The media player decompresses the multimedia content and begins the playback after some buffering time in order to remove the variation in the source-to-destination packet delay. This variation is usually called *delay jitter*. Removing the delay jitter is essential because multimedia data must be presented to the user with the same timing as the original recording. The media player also performs error correction in order to handle packet losses caused by network congestion. Figure 1 further explains the streaming process. Note that the Web and streaming servers can be

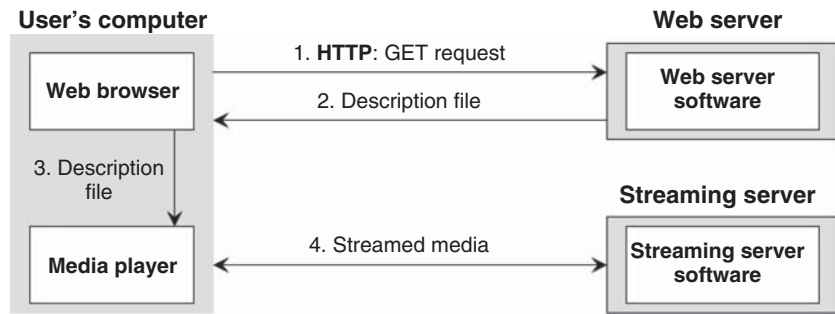

Figure 1: Multimedia streaming process

implemented on the same machine. The connection between the streaming server and the client is bidirectional because of user interactions.

Let us now discuss in more detail the communication between the streaming client and the streaming server. This communication usually involves coordination among three application-layer protocols: *real-time streaming protocol* (RTSP), *real-time protocol* (RTP), and *real-time control protocol* (RTCP). The functions of these protocols can be explained as follows:

- RTSP manages the streaming session. In particular, it is used to initiate and control the delivery of multimedia streams. Basically, it supports such user interactions as play, pause, resume, fast forward, fast rewind, and stop (teardown).
- RTP provides end-to-end delivery services for multimedia streams such as payload type identification, sequence numbering, and time stamping. It can be viewed as a sublayer of the transport protocol. It runs on top of the *user datagram protocol* (UDP) or the *transport control protocol* (TCP). UDP, however, is preferable for multimedia streaming as will be explained later.
- RTCP supports monitoring of data delivery and provides intermedia synchronization and participant identification services.

Figure 2 illustrates the coordination among these protocols through a simple example. After retrieving the description file, the client issues the RTSP setup command, and the server responds by establishing an RTSP session and informing the client. The client then issues the play command, and the server replies by granting the request.

Now the delivery of the stream begins, using the transport protocol specified by the setup command (RTP/UDP in this example). RTCP is used as well to provide important control information. Finally, the client issues the RTSP teardown command to stop the streaming service. Although not shown in this figure, the client can apply other interactive operations, such as pause and resume, during the RTSP session. The example shows only one multimedia stream, but there can actually be more than one stream. For instance, a movie may be delivered in separate audio and video streams. In such a case, RTCP can help synchronize these streams.

STREAMING PROTOCOLS

We now discuss in more detail the network protocols used for streaming.

Real-Time Streaming Protocol

RTSP is a control protocol defined by IETF RFC 2326. Its function resembles a VCR remote control. RTSP manages the streaming session but does not deliver the data by itself (although its connection may be used in certain cases to tunnel RTP traffic). It uses text-based messages, which can be transported using TCP or UDP. RTSP is generally similar to HTTP, but with significant differences. For example, RTSP supports both client-to-server and server-to-client requests. Moreover, RTSP maintains a session state (whereas HTTP is stateless). Furthermore, the data with RTSP are carried out-of-band using another protocol, typically RTP.

Table 1 lists and describes various types of RTSP requests. The setup request creates an RTSP session for the

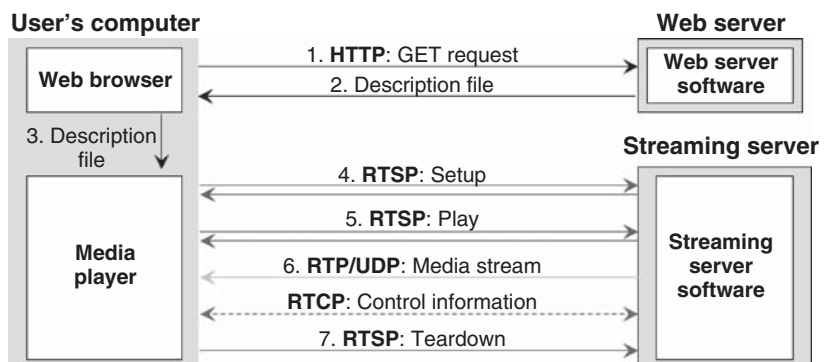

Figure 2: Coordination among different protocols in multimedia streaming

Table 1: Types of RTSP Requests

Method	Direction	Desired Action
DESCRIBE	C → S	Server returns a description of the presentation or object
ANNOUNCE	C → S	Client posts description to server
	S → C	Server updates session description
OPTIONS	C ↔ S	Requester determines options supported by the other part
SETUP	C → S	Server allocates resources and creates a session
PLAY	C → S	Server starts sending data
RECORD	C → S	Clients starts recording a data stream
PAUSE	C → S	Server halts the delivery temporarily
REDIRECT	S → C	Client connects to a another server
GET_PARAMETER	C ↔ S	Server or client retrieves a parameter value
SET_PARAMETER	C ↔ S	Server or client changes a parameter value
TEARDOWN	C → S	Server stops stream delivery and frees resources

specified presentation or multimedia object. All later requests by the client must include the generated session number. The play request supports absolute positioning by specifying the range within the stream to be played out. Fast forward and fast rewind can be requested by specifying the speed value.

Real-Time Protocol

Streaming applications typically employ RTP, which is defined by IETF RFC 3550. Basically, it provides end-to-end delivery services for real-time data, including payload type identification, time stamping, sequence numbering, and source identification. These services can be described as follows:

- **Payload identification:** The payload type field in the RTP header identifies the format of the RTP payload and determines how it can be interpreted by the application. Examples of payload types are PCM, MPEG audio, motion JPEG, H.262, MPEG-1 video, and MPEG-2 video.
- **Time stamping:** The time stamp field in the header reflects the sampling instant of the first byte in the RTP data packet. The receiver uses the time stamps to remove the packet delay jitter introduced by the network and thus reconstruct the original timing of the multimedia content.
- **Sequence numbering:** The sequence number field in the header is incremented by one for each RTP data packet sent. It can be used by the recipient to detect any packet loss and thus perform the necessary correction action.
- **Source identification:** The *synchronization source identifier* (SSRC) field in the header identifies the source of the RTP stream. Each source generates a random number when its stream starts and uses the number as an identifier. (The RTP implementation should make sure that each source will have a unique identifier.) In some situations, a participant may generate multiple streams in

an RTP session. For example, one stream can be from a microphone and another from a camera. In such situations, each source must have a different SSRC.

RTP also supports delivery to multiple recipients using multicasting when this service is provided by the network.

Real-Time Control Protocol

RTCP is a control protocol that works along with RTP. It is also specified by IETF RFC 2326. RTCP packets do not encapsulate RTP packets or any parts of multimedia data. They are separate packets that are sent periodically to give feedback on the quality of data distribution and to provide membership information.

Let us now discuss the different types of RTCP packets.

- **Receiver report (RR):** This packet contains the reception statistics from participants who are not active senders for each stream they receive. These statistics include the last sequence number received, the fraction of packets lost, the largest packet number received, and the interarrival jitter for each RTP stream.
- **Sender report (SR):** This packet includes both reception and transmission statistics for participants who are active senders. The reception statistics are the same as those in RR, but the transmission statistics contain the number of packets sent and the number of bytes sent. In addition, SR contains important information for inter-media synchronization: RTP time stamps and their corresponding *network time protocol* (NTP) time stamps. (NTP time stamps indicate the wall clock time.)
- **Source description items (SDES):** This packet contains textual information that describes a source, such as the participant's name, telephone number, and e-mail address.

- **BYE:** This packet is used to indicate the end of participation.
- **Application-specific functions (APP):** This packet is intended for experimental use as new applications and features are developed.

These RTCP packets can be used to provide the following services.

- **Quality of service (QoS) monitoring and congestion control:** The primary function of RTCP is to provide feedback on the quality of data distribution. This function is related to TCP's congestion and flow control functions. The shared reception and transmission statistics help senders, receivers, and network managers. In particular, senders can adjust their transmission rates (by changing the encoding for instance), while receivers can know whether the congestion is local, regional, or global. On the other hand, network managers can use the feedback information to evaluate the performance of multicast distribution.
- **Intermedia synchronization:** RTP multimedia streams may advance at different rates. They also typically have different time offsets to prevent some possible security attacks. Hence, the SR of an active sender contains the current RTP time stamp of the stream and its corresponding wall clock time. This information can be used by receivers to synchronize different incoming streams. For instance, a receiver can use the information to perform lip synchronization for a video.
- **Source identification:** This function is performed by sending SDES packets so that participants in a session will know each other.
- **Control information scaling:** The frequency of sending RTCP packets should be controlled in order to prevent the control traffic from overwhelming the network. RTCP limits the control traffic to at most 5 percent of the overall session traffic.

STREAMING OVER THE INTERNET: CHALLENGES AND APPROACHES

Streaming multimedia over the Internet faces significant challenges. The Internet provides only a best effort service, thus there are no guarantees whatsoever on bandwidth, delay jitter, or packet-loss rate. The best effort service works well for many applications, such as Web browsing, FTP, and e-mail but, unfortunately, it is not well suited for multimedia streaming. The time-varying bandwidth, packet delay, and packet loss make accessing multimedia data in real time challenging.

We now discuss the main approaches and techniques used to address these challenges.

Rate Control and Rate Shaping

The available bandwidth between any two nodes on the Internet is unknown and varies with time. Sending data at a higher rate than the available bandwidth leads to network congestion and subsequently packet loss, while sending data at a lower rate underutilizes the bandwidth

and possibly reduces audio and video quality. Thus, congestion control is required. For multimedia streaming, congestion control requires two mechanisms: *rate control* and *rate shaping*. Rate control estimates the available bandwidth and determines the data's transfer rate based on the available bandwidth. Rate shaping, on the other hand, forces the source (streaming server) to send the stream at the rate determined by rate control.

Rate Control

Multimedia data can be streamed by using TCP, which employs an *additive increase, multiplicative decrease* (AIMD) rule. The transmission rate is increased at a constant rate when no congestion is inferred (based on packet loss, delay, or delay jitter); otherwise, the transmission rate is halved. Using TCP for streaming multimedia causes serious problems. First, TCP retransmits lost packets to live up to its guarantees of reliable communication. Such retransmissions amplify the already high delay in the delivery of packets. These retransmissions, however, may not be necessary because multimedia data is loss tolerant. In particular, packet losses cause glitches, which can be concealed partially or fully (as will be discussed later). Second, the AIMD rule leads to wide variations in the instantaneous throughput (in the form of a sawtooth pattern). These variations are problematic for multimedia streaming. Third, TCP has a slow-start phase. Hence, the UDP is usually preferable to TCP. UDP's transmission rate can be controlled in a TCP-friendly manner by matching TCP throughput on a macroscopic scale while avoiding the wide variations in instantaneous throughput (Mathis, Semke, and Mahdavi 1997; Padhye et al. 2000; Tan and Zakhor 1999; Floyd et al. 2000).

Rate control can be performed by the source or the receiver. Source-based rate control is inefficient when a multimedia stream is sent to multiple recipients using multicasting (i.e., one-to-many communication). For such an environment, a receiver-based technique called *layered multicast* (McCanne, Jacobson, and Vetterli 1996) can be used. This technique uses *layered compression* schemes, which encode the multimedia file into a *base* layer and one or more *enhancement* layers. The base layer provides low but acceptable and usable quality, whereas each enhancement layer refines the quality further. With the layered multicast technique, the source transmits each layer on a separate multicast channel, while the receiver determines the number of channels to listen to based on the current network condition. The receiver changes the number of channels dynamically by adding channels when no congestion is detected and dropping channels when congestion occurs.

Although TCP is less suitable than UDP for streaming multimedia, TCP accounts for the majority of streaming traffic over the Internet (Merwe, Sen, and Kalmanek 2002). A primary reason for UDP's limited usage is that many network administrators close their firewalls to UDP traffic. The study (Wang et al. 2004) shows that TCP generally provides satisfactory streaming performance when the achievable TCP throughput is roughly twice the multimedia bit rate. The performance was considered satisfactory when the fraction of late packets was less than 10^{-4} for a startup delay of approximately 10 seconds.

Rate Shaping

The question arises now as to how the compressed multimedia object can be “shaped” or transformed to fit the available bandwidth. This is the function of rate shaping. Several techniques can be used for rate shaping, including *transcoding*, *multirate switching*, and *layered compression*. These can be described as follows.

- With transcoding, the video or audio is decoded and then re-encoded to the desired bit rate. Unfortunately, transcoding requires extensive computations and produces video and audio quality that is worse than if the streamed content were to be encoded directly at the target bit rate.
- With multirate switching, multiple copies of the multimedia object are made available at different bit rates, each of which targets a common network connection speed (such as dialup modem, DSL, cable, T1 line, etc.). The client can switch dynamically during the streaming session from one bit rate to another that best suits the current available bandwidth. This technique removes effectively both shortcomings of transcoding. It increases, however, the required storage capacity and has limited ability to adapt to the current bandwidth because only a small number of copies, and thus a small number of target bit rates, can practically be made available in actual servers.
- Layered video compression encodes the video into multiple layers and lets the client determine the number of received layers. Unfortunately, data overlap among the different compression layers reduces the compression efficiency compared with nonlayered schemes. The overall storage requirement, however, is much smaller than multirate switching.

Client-Side Buffering

The streamed multimedia content should be played back at a constant rate. For instance, a video recorded at 30 frames/sec should be played back at that same rate. Streaming that file through the Internet leads to variations in the end-to-end packet delays (delay jitter). The delay jitter causes perceptual problems in the reconstructed video. Hence, a playout buffer can be used at the receiver (the client side) to smooth out the variations in the packet delay. Buffering can also absorb, to a certain degree, the variability in the available bandwidth. Unfortunately, these advantages come at the expense of increasing the initial delay.

Error Control

As discussed earlier, UDP is more suitable than TCP for transporting multimedia data. Because UDP does not ensure reliable delivery, the purpose of error control is to address the problem of packet loss that would otherwise severely degrade the playback quality. Error control techniques can be classified into four main classes: *forward error correction*, *delay-constrained retransmission*, *error-resilient coding*, and *error concealment*.

Let us now briefly discuss the different error control approaches. Additional information can be found in

Wang and Zhu (1998); Wang, Ostermann, and Zhang (2002); and Apostolopoulos, Tan, and Wee (2002).

Forward Error Correction

Forward error correction (FEC) adds redundant information that can be used in the case of packet loss to reconstruct the original information. For example, a video stream can be divided into segments, each of which is packetized into k packets of actual data and l packets of error control information. A segment can be reconstructed fully if any k packets are received correctly. Otherwise, the perceptual quality might be affected if no further error control is provided.

Delay-Constrained Retransmission

As mentioned earlier, UDP does not retransmit lost packets so as to avoid any additional delays. In certain situations, however, it may be desirable to retransmit a lost packet, particularly if the expected delay will be within a certain range. For example, delay-constrained retransmission can be implemented by the receiver as follows. When the receiver detects the loss of a packet, it sends a request to the server to retransmit that packet if

$$T_{curr} + RTT < T_{disp} + T_s \quad (1)$$

where T_{curr} is the current time, RTT is the network round trip time, T_{disp} is the time the packet is scheduled for display, and T_s is a safety threshold. Otherwise, the receiver relies on error concealment to deal with the packet loss.

Error-Resilient Coding

The error-resilient coding approach addresses the packet-loss problem from the compression perspective by changing the compression algorithm so that it can be resilient to some types of error caused by packet loss. Current video compression standards use motion-compensated prediction between frames and block-based spatial transforms (such as DCT) for each frame, followed by entropy encoding (such as Huffman coding). These standards are highly susceptible to packet loss, which may cause significant error propagation and loss of bit stream synchronization. Thus, the purpose of error-resilient coding is to limit error propagation and reduce the scope of error in the reconstructed video or audio.

Error Concealment

Error concealment tries to minimize the negative impact of packet loss on the perceptual quality of the multimedia content. Basically, the lost information can be predicted based on other received information. For example, videos exhibit significant degrees of spatial locality (within frames) and temporal locality (between frames) that can be used to interpolate the missing information. Generally, there are three main approaches for error concealment: *spatial interpolation*, *temporal interpolation*, and *motion-compensated temporal interpolation*.

- With spatial interpolation, missing pixels in a frame can be interpolated based on neighboring pixels in the same frame.

- Temporal interpolation uses the corresponding pixels in a correctly received previous frame. This approach does not consider any possible motion between the two frames and thus is effective only for low-motion videos.
- Motion-compensated temporal interpolation is more effective for high-motion videos. Basically, it considers possible movements (which can be detected by examining motion vectors) in predicting the missing information.

Other Approaches

The shortcomings of the Internet's best-effort service can be mitigated in many other ways, including the following:

- *Internet service providers (ISPs)* can reduce packet delay and packet loss by adding more bandwidth and switching capacity.
- Multicasting can be employed to use server bandwidth and network resources efficiently. It can be implemented at the IP level (Giuliano undated; SprintLink undated), which is most effective but challenging and currently not widely deployed. It can also be implemented at the application level by using *multicast overlay networks* (Jannotti et al. 2000; Chu, Rao, and Zhang 2000; Castro et al. 2002). The overlay consists of multiple servers scattered across the network.
- ISPs can use *Web caching* (also called *proxy caching*) to bring the content closer to the clients and to reduce the traffic on the access links of these ISPs to the Internet.
- *Content delivery networks (CDNs)* can be used to replicate multimedia files and place them at the edges of the Internet closer to the clients.

The need for the Internet, however, to provide services beyond the best-effort service has grown spectacularly. Therefore, many frameworks have been developed for providing QoS. These frameworks include the *integrated services* (IntServ) model (Clark, Shenker, and Zhang 1992; Braden, Clark, and Shenker 1994; Braden et al. 1997; White 1997) and the *differentiated services* (DiffServ) model (Blake et al. 1998; Bernet et al. 1998). The IntServ model requires fundamental changes to the Internet so that applications can reserve bandwidth in each link between the sender and the receiver. This model uses the *resource reservation protocol* (RSVP) (Braden et al. 1997; Guerin, Blake, and Herzog 1997; Li and Rekhter 1998) to set up paths and reserve resources along them. In contrast, the DiffServ model requires only minor changes to the Internet by introducing only few classes and giving packets differentiated services based on their assigned classes. The reader is recommended to refer to Xiao and Ni (1999) and Kurose and Ross (2004) for additional information on Internet QoS.

STREAMING SERVER DESIGN

Streaming servers face significant challenges to support large numbers of concurrent customers because of the requirements of real-time playback and high transfer rates. This section focuses on servers that stream stored

multimedia content, *video on demand* (VOD) servers in particular. The design of these servers is more challenging than live-streaming servers because multiple clients of the same video can be at different playback points and unrestricted support for interactive operations is desirable.

We now discuss the main design aspects for streaming servers: admission control, resource sharing, request scheduling, and storage subsystem management.

Admission Control

The basic function of the admission control unit is to ensure that the real-time performance requirements of all admitted requests are met. There are three main approaches for admission control: *deterministic* (Ferrari 1990; Gemmell and Christodoulakis 1992; Cheng, Chen, and Chen 2000), *predictive* (Vin et al. "Admission control," 1994; Bao and Sethi 1999), and *statistical* (Vin, Goyal, and Goyal 1994; Zimmermann and Fu 2003). The deterministic approach provides hard QoS guarantees by admitting new requests only if the real-time requirements of all existing requests are guaranteed to be met. Thus, this approach must assume the worst case for system parameters (including the disk seek time, rotational latency, and transfer rate). The predictive and statistical approaches increase the utilization of resources by providing soft QoS guarantees. Hence, they admit new requests if the real-time requirements of existing requests are *likely* to be met. Both of these approaches reach their decisions by using statistical analysis. The predictive approach uses actual measurements of server utilization, whereas the statistical approach is entirely parameter-based.

Resource Sharing

Streaming servers—VOD servers, in particular—can support limited numbers of concurrent customers because of the required real-time and high-rate transfers. Resource-sharing techniques face this challenge by using the multicast facility and exploiting the high locality of reference in multimedia access patterns. The main classes of resource-sharing techniques include *batching*, *stream merging*, and *periodic broadcasting*. These classes are briefly discussed below, but only some of the more popular techniques are covered.

Batching

With batching, the requests to the same videos are accumulated and serviced together by utilizing the multicast facility. Batching, therefore, offloads the underlying storage subsystem and efficiently uses server bandwidth and network resources.

Stream Merging

Stream-merging techniques combine streams when possible to reduce the delivery costs. These techniques include *stream tapping and patching* (Carter and Long 1997; Hua, Cai, and Sheu 1998), *transition patching* (Cai and Hua 1999), and *hierarchal stream merging* (Eager, Vernon, and Zahorjan 1999, 2001).

Patching expands the multicast tree dynamically to include new requests. A new request joins immediately

Figure 3: Clarification of patching

Figure 4: Clarification of transition patching

the latest multicast stream for the object and receives the missing portion as a patch using a unicast stream. When the playback of the patch is completed, the client continues the playback of the remaining portion using the data received from the multicast stream and already buffered locally. The cost of servicing a new request is determined by its temporal skew to the latest multicast stream. To avoid the continuously increasing cost of patch streams, regular streams (i.e., multicast streams of the whole video) are typically retransmitted every prespecified period of time, which is called *regular window* (W_r). Figure 3 further explains the concept. In the figure, D is the video length in seconds. Typically, W_r is much smaller than D , but the figure is meant only for a simple clarification.

Transition patching allows some patches to be sharable by extending their lengths. It introduces another multicast stream called *transition patch*. The threshold to start a regular stream is W_r as in patching, and the threshold to start a transition patch is called the *transition window* (W_t). The transition patch length is equal to the difference between the starting times of the transition patch and the last regular stream plus $2 \times W_t$, whereas the length of the patch is equal to the difference between the starting times of the patch and the latest transition stream or regular stream. Hence, the maximum possible patch length is W_t , and the maximum possible transition patch length is $W_r + 2 \times W_t$. Figure 4 further illustrates the concept. A possible scenario for a client is to start listening to its own patch and the transition patch; when its patch is completed, it starts listening to the regular stream.

Both patching and transition patching are extended with *hierarchical stream merging*, whereby streams can merge multiple times during their lifetimes to form dynamic merge trees. Eager, Vernon, and Zahorjan (1999) analyzed different policies for creating merge trees. The best performer among these policies is *earliest reachable merge target* (ERMT). With ERMT, which was shown to perform near optimally, a new client or a newly merged group of clients snoops on the closest stream that it can merge with if no later arrivals preemptively catch them.

Periodic Broadcasting

Periodic broadcasting protocols divide each supported multimedia object (usually video) into multiple segments and broadcast them periodically on dedicated server channels. Thus, they can service unlimited numbers of customers but can be used only for the most popular objects, and they require customers to wait until the next broadcast times of the first segments. Note that as the number of segments increases, the maximum waiting time shortens (because the length of the first segment is reduced). A large number of broadcasting techniques has been proposed. These techniques differ in terms of the maximum waiting time achieved by the same server bandwidth, the required client download bandwidth, and buffering space.

Basically, broadcasting protocols can be classified into the following three main classes (Hu 2001):

- Class A partitions the objects into increasing size of segments and transmits them periodically on dedicated logical channels. This class is based on the idea of *pyramid broadcasting* (Viswanathan and Imielinski 1995) and includes *skyscraper broadcasting* (SB) (Hua and Sheu 1997) and *fast broadcasting* (FB) (Juhn and Tseng 1998). Both SB and FB allocate each channel a fixed bandwidth, b , that is equal to the object consumption (playback) rate. SB partitions the segment according to the series $\{1, 2, 2, 5, 5, 12, 12, 25, 25, 52, 52, \dots\}$. The partitioning series determines the relative segment size. (Note that the first segment is the smallest in order to reduce the maximum waiting time.) SB requires the client to download from only two channels at any one time. FB, however, employs the partitioning series $\{1, 2, 4, \dots, 2^{K-1}, 2^K\}$, where K is the number of channels. FB is more efficient in server bandwidth, but it requires the client to download from all channels. Other protocols in this class include *Fibonacci broadcasting* (Hu 2001) and *reliable periodic broadcast* (Mahanti et al. 2003).
- Class B partitions objects into equal-sized segments and transmits them in logical channels of decreasing

bandwidth. Thus, it requires much less server bandwidth than class A. Using segments of increasing size is less efficient because each entire segment must be broadcast at the same bandwidth and periodicity while the data at the end of a segment could have been broadcast at lower bandwidth (Pâris, Carter, and Long 1999). This class is based on *harmonic broadcasting* (HB) (Juhn and Tseng 1997), which allocates channel i bandwidth b/i . The client here is required to download from all channels simultaneously. HB may not be able to meet the real-time playback requirements in certain cases. This problem was resolved by later HB-based techniques, including *cautious harmonic* (Pâris, Carter, and Long “Efficient broadcasting,” 1998), *quasi harmonic* (Pâris, Carter, and Long “Efficient broadcasting,” 1998), and *polyharmonic* (Pâris, Carter, and Long “Low bandwidth, 1998).

- Class C is a hybrid of classes A and B. It is based on *pagoda broadcasting* (Pâris, Carter, and Long 1999) and uses fixed-length segments like class B and equal bandwidth logical channels like class A. The main objective is to reduce the number of logical channels that should be managed by the server compared with HB while achieving close reductions in server bandwidth. Thus, Pagoda broadcasting divides each object into fixed-size segments and maps segments to a small number of logical channels of equal bandwidth and uses time-division multiplexing to ensure that successive segments are broadcast at the proper decreasing frequencies.

Qudah and Sarhan (2006) provide additional information and a detailed analysis of resource-sharing techniques.

Request Scheduling

VOD servers maintain a waiting queue for each video. The purpose of the scheduling unit is to select for service an appropriate queue whenever the server has sufficient resources. Many scheduling policies exist, including *first-come, first-served* (FCFS) (Dan, Sitaram, and Shahabuddin 1994), *maximum queue length* (MQL) (Dan, Sitaram, and Shahabuddin 1994), and *maximum factored queue length* (MFQL) (Aggarwal, Wolf, and Yu 2001). They can be described as follows:

- FCFS acts fairly by selecting the queue with the oldest request.
- MQL maximizes the number of requests serviced at any time by selecting the longest queue. It is, however, extremely biased against unpopular objects because they have shorter queue lengths.
- MFQL attempts to minimize the mean request waiting time by selecting the queue with the *largest factored queue length*. The factored length of a queue is defined as its length divided by the square root of the relative access frequency of its corresponding video. MFQL is more fair toward unpopular objects than MQL but less fair than FCFS.

A detailed analysis of scheduling policies can be found in Sarhan and Das (“Simulation,” 2003). In Sarhan and Das (“New class,” 2004), a new class of scheduling policies for

providing time-of-service guarantees was proposed. Providing time-of-service guarantees can enhance customer-perceived QoS and influence customers to wait, thereby increasing server throughput.

Storage Subsystem Management

Storage subsystems play a significant role in the performance, scalability, and reliability of multimedia servers. The main design aspects of multimedia storage subsystems include *disk striping*, *fault tolerance*, and *cache management*.

Disk striping (Shenoy and Harric 1999) is used to increase the disk I/O bandwidth.

To address the reliability problem of hard disk drives, multimedia servers employ fault-tolerance techniques that can be classified as either *parity-based* (Berson, Golubchik, and Muntz 1995; Tewari et al. 1996) or *mirror-based* (Mourad 1996; Haskin 1998).

The objective of cache management is to reduce the load on the storage subsystem by caching portions of the multimedia data (videos in particular) in the main memory of the server. *Interval caching* (Dan et al. 1995) is a cache-management technique that exploits the locality of reference by caching intervals between successive streams. Basically, it attempts to pair each playback request with an immediately preceding request for the same video that is currently being serviced. When the server accepts a request for service from the cache, it starts to cache the data of the preceding stream while retrieving and transferring them to the client, and the compression method used. Interval caching uses the available cache (memory) space efficiently by ensuring that only the shortest intervals are cached at any time. *Generalized interval caching* (Dan and Sitaram 1996) extends interval caching to handle workloads of short and long videos. It does not require paired streams to be concurrent because short videos are unlikely to have concurrent accesses. Hence, when two paired streams are not concurrent, the technique caches the entire corresponding video. Interval caching has also been adapted to cache multimedia data in network-attached disk environments (Sarhan and Das “Integrated resource,” 2003; “Caching,” 2004).

Cache management is essential, regardless of the resource-sharing techniques used. Interval caching works well with batching, but it is not well suited for other resource-sharing techniques such as patching, transition patching, and ERMT. In Qudah and Sarhan (2006), a statistical approach for cache management was proposed for multimedia servers using various resource-sharing techniques. With this approach, the server periodically computes video access frequencies and determines the data to be cached. Besides being performance effective, this approach is easy to implement and incurs small overhead because updates are triggered only when the workload varies considerably. The results show that this approach for cache management is highly effective in reducing the disk I/O bandwidth requirements. For example, with a cache size of only 2 percent of the total size of videos, these requirements can be reduced by as much as 16 percent for systems with moderate request rates. Moreover, these reductions increase with the request arrival rate.

CONCLUSION

Streaming multimedia data over the Internet is typically performed by coordination among three application-layer protocols: *real-time streaming protocol* (RTSP), *real-time protocol* (RTP), and *real-time control protocol* (RTCP). RTSP manages the streaming session and supports user interactions, while RTP provides end-to-end delivery services for multimedia streams, including payload type identification, sequence numbering, and time stamping. RTCP is used to support monitoring of the data delivery and provide intermedia synchronization and participant identification services.

Multimedia streaming presents serious challenges to both the network and the server. The Internet provides only a best-effort service and thus makes no guarantees on bandwidth, delay jitter, or packet-loss rate. The best-effort service works well for many applications but is not well suited for multimedia streaming. The main ways to mitigate the shortcomings of the best-effort service can be summarized as follows:

- UDP can be used instead of TCP not only to avoid the additional delays caused by retransmitting lost packets but also to avoid the wide variations in the instantaneous available bandwidth.
- Rate-control and rate-shaping techniques can be used to address the time-varying available bandwidth. Rate control estimates the available bandwidth and determines the data-transfer rate based on the available bandwidth; rate shaping forces the source (streaming server) to send the stream at the rate determined by rate control using transcoding, multirate switching, or layered compression. When a multimedia stream is sent to multiple recipients using multicasting, receiver-based rate control is more suitable than source-based. With receiver-based rate control, the multimedia object is encoded into multiple layers that are transmitted separately, and the recipient determines the number of layers to listen to, dynamically based on its available bandwidth to the source.
- The client can use a playout buffer to smooth out the delay jitter and absorb (to some degree) the variability in the network bandwidth.
- Error-control techniques can be employed to handle packet loss when UDP is used. These techniques can be classified into four main categories: *forward error correction* (FEC), *delay-constrained retransmission*, *error-resilient coding*, and *error concealment*. FEC adds redundant information that can be used to reconstruct the missing data. With delay-constrained retransmission, lost packets are retransmitted if they are expected to arrive before their scheduled playback time. Error-resilient coding changes the compression algorithm to be resilient to some errors caused by packet loss. Error concealment exploits the spatial and temporal locality of multimedia data by interpolating the missing information.

The design of streaming servers—*video on demand* (VOD) servers, in particular—faces a significant challenge to support large numbers of concurrent requests. Without

smart management of server resources, the network bandwidth and disk I/O bandwidth will be consumed quickly after servicing only a small number of customers. Resource-sharing techniques such as stream merging and periodic broadcasting face this challenge by utilizing the multicast facility. Stream-merging techniques combine streams when possible to reduce the delivery costs, whereas periodic protocols divide each supported multimedia object into multiple segments and broadcast them periodically on dedicated server channels. Request scheduling, admission control, and storage management are other important design aspects that can significantly affect the server's overall performance. To meet the high disk I/O bandwidth requirement, multimedia objects are typically striped across multiple disks that can be accessed concurrently.

ACKNOWLEDGMENT

I would like to thank the anonymous reviewers for their insightful and helpful comments and suggestions.

GLOSSARY

Batching: A resource-sharing technique that accumulates requests for the same multimedia streams and services them together using multicasting.

Error control: A variety of techniques used to deal with packet loss and data corruption. The main classes of error-control techniques for multimedia streaming are *forward error correction*, *delay-constrained retransmission*, *error-resilient coding*, and *error concealment*.

Multimedia streaming: Pipelining the delivery and playback of multimedia data.

Periodic broadcasting: A group of resource-sharing techniques that divide multimedia objects into segments and broadcast them periodically on dedicated server channels. They include *skyscraper broadcasting*, *harmonic broadcasting*, and *pagoda broadcasting*.

Rate control: A congestion control mechanism that estimates the available bandwidth and determines the data-transfer rate based on the available bandwidth.

Rate shaping: A congestion control mechanism that forces the data source (streaming server) to send the stream at the rate determined by rate control.

Real-time control protocol (RTCP): A network protocol used in conjunction with *real-time protocol* (RTP) to support the monitoring of data delivery and provide intermedia synchronization and participant identification services.

Real-time protocol (RTP): A network protocol that provides end-to-end delivery services for multimedia streams. These services include *payload type identification*, *sequence numbering*, and *time stamping*.

Real-time streaming protocol (RTSP): A network protocol that manages streaming sessions of multimedia data. It supports such user interactions as play, pause, resume, fast forward, fast rewind, and stop (teardown).

Resource sharing: Techniques that reduce the delivery costs of multimedia streams by using multicasting. The main classes of resource sharing techniques are *batching*, *stream merging*, and *periodic broadcasting*.

Stream merging: A group of resources sharing techniques that combine some multimedia streams (when possible) to reduce the delivery costs. These techniques include patching, transition patching, and earliest reachable merge target (ERMT).

INTRODUCTION

Ever since the first black-and-white television image was displayed, both developers and viewers have sought ways to make it better: to add more resolution, to increase the contrast ratio, and to be able to faithfully replicate the color spectrum. An obvious yardstick to measure the progress and quality of television has been cinematic film, which for years has been capable of providing high-resolution moving images. Imagine TV developers in 1939 who watched the cinematic premiere of *The Wizard of Oz* or *Gone with the Wind*. What would they think after returning to their homes to face the comparatively small and grainy images on black-and-white television sets?

With *high-definition television* (HDTV), the gap has narrowed. George Lucas shot the last additions to his popular *Star Wars* collection using high-definition video cameras. More and more HDTV sets have made their way into a growing number of residential households. Despite the fact that we are closer than ever to having a high-definition cinema experience in all of our homes, obstacles remain. Broadcasters need cost-effective production tools. Consumers want to be able to purchase, record, and play back their favorite programs easily and at relatively low cost. The Federal Communications Commission (FCC) planned to end all analog television broadcasts by 2006, but recent legislation pushed this cutoff date back to February 17, 2009.

As we consider HDTV, it is useful to trace its evolution and maintain some perspective. *High definition* is a relative term. It is higher resolution—but higher than what?

This chapter will examine the environment in which HDTV has developed and identify some of its more important technical characteristics.

HISTORY OF TELEVISION

The exact beginning of what most of us refer to as television is debatable. In 1842, Alexander Bain managed to transmit a still image over wire, inventing what can readily be called the first fax machine. In 1884, Paul Gottlieb Nipkow went a step further and discovered (and patented) a way to scan a moving image and transmit it sequentially. Nipkow's process used two synchronized spinning disks, each with a spiral pattern of holes in it. On the transmitting side, a disk was placed between the subject and a light-sensitive element. The receiving side had a similar disk placed between a light source and the viewer. The resolution of Nipkow's disk system depended on the number of holes in the disk. His system was thought to have been able to achieve between eighteen and thirty lines of resolution and marked the beginning of the era of electro-mechanical television.

However, John Logie Baird, a Scottish inventor, publicly demonstrated what some consider the first recognizable video image of a human face on January 26, 1926. Baird's gray-scale image, presented to members of the Royal Institution in London, had only some thirty lines of resolution. Baird used a spinning disk similar to Nipkow's that was embedded with lenses and provided an image just clear enough to display a human face. Baird's television

proved to be popular. His company, Baird Television Development Company, continued working to improve and refine the image. The maximum resolution ever achieved by his electromechanical system was approximately 240 lines (British Broadcasting Corporation undated).

But electromechanical television was cumbersome, and interest diminished as developers realized that an electronic process was necessary in order to provide higher levels of resolution. In 1934, Philo Farnsworth gave a public demonstration of an all-electronic system. The system used a camera on one end and a *cathode ray tube* (CRT) to serve as a display on the receiving end. Both camera and CRT used an electron beam controlled by modulating a magnetic field. Compared to electromechanical TV, the all-electronic system was more convenient and interest in TV broadcasting soared. Other developers soon began developing improved versions of television and began successfully marketing them to the public.

The Search for Standards: The FCC and the NTSC

The FCC oversees radio, wire, cable, satellite, and television broadcast in the United States. Established by the Communications Act of 1934, the FCC initially set out to regulate the ever-increasing use of the broadcast spectrum. One of the FCC's early challenges was setting technical standards for television. In 1936, the Radio Manufacturers Association (RMA) recommended a standard for television using 441 horizontal scan lines and 30 frames per second (fps) with a 4:3 aspect ratio. The public was accepting of the 4:3 aspect ratio because it was close to existing 16- and 35-millimeter (mm) film formats, which used the *Academy aperture* (an 11:8 aspect ratio). A major manufacturer, the Radio Corporation of America, embraced this standard and had already begun broadcasting and manufacturing TV receivers capable of displaying 441 scan lines.

Many opponents, however, argued that more picture detail was necessary. After a series of formal hearings, the FCC urged the RMA to form the *National Television System Committee* (NTSC) in 1940. Its goal was to set technical standards for the broadcast of black-and-white television. The next year, the NTSC established its first set of standards; they kept the 4:3 aspect ratio but called for a higher resolution image with 525 scan lines refreshing at a rate of 30 interlaced frames (or 60 fields) per second. Each interlaced frame consisted of two fields. First, the odd lines were scanned for field 1, then the even lines were scanned for field 2. Television stations were allotted 6 MHz of bandwidth per channel, which ultimately covered a frequency range spanning from 54 MHz to 890 MHz on the broadcast spectrum.

Color Television

In order for signals to broadcast color, the original NTSC standard for black-and-white television had to be revised. NTSC presented an update in 1953. Creating the new standard was no easy task because engineers had to make color broadcasts backward-compatible with the large base of existing black-and-white televisions (ten million sets had been sold by 1949). To do so, engineers split the

signal into two components: (1) *luminance*, referred to as *luma*, which contained the brightness information; and (2) *chrominance*, which contained the color. The color information was encoded onto a 3.58-MHz subcarrier added onto the video signal. Black-and-white sets could ignore the color subcarrier using only the *luma* portion while color sets could take advantage of both. Unfortunately, the color subcarrier interacted with the sound carrier, creating minor visible artifacts. To reduce interference, the field refresh rate of 60 Hz was slowed down by a factor of 1000/1001 to 59.94 Hz. Instead of running at 30 fps, broadcast television downshifted to 29.97 fps.

PAL and SECAM

Although the United States, Canada, and Mexico adopted NTSC standards based on a 60-Hz frequency, most other countries developed color television systems based on 50 Hz. (The refresh frequencies varied because they were dependent on the operating frequency of a region's electrical systems.) Most versions of *phase alternating line* (PAL) and *séquentiel colour avec mémoire* (SECAM), while still employing a 4:3 aspect ratio, had 625 horizontal scan lines. The 100 extra scan lines provided more picture detail but some people felt the slower 25-Hz scan rate created a noticeable flicker.

High-Definition Advances

During the next thirty years, many improvements were made in cameras, production and broadcast gear, and television receivers. Despite these advances, the quality of analog broadcast was still limited to the NTSC standard of 60 fields and 525 horizontal scan lines. To take television to the next level, the entire analog broadcasting system had to be replaced. Several manufacturers had developed and were already using *high-definition* (HD) digital television systems. The exact format had yet to be determined, but it was clear that the replacement for analog would use digital television technology. What was needed was a set of standards to ensure compatibility.

Advanced Television Systems Committee

In 1982, industry associations, corporations, and educational institutions formed the Advanced Television Systems Committee (ATSC). This not-for-profit organization develops voluntary standards for advanced television systems, including enhanced analog TV, *digital TV* (DTV), *standard definition TV* (SDTV), *high-definition TV* (HDTV), and data services. The ATSC's published broadcast standards are voluntary unless adopted and mandated by the FCC.

In 1987, The FCC formed an advisory committee on advanced television service. The goal was to explore the issues of advanced television technologies and to advise the FCC in both technical and public policy matters accordingly. By 1989, there were as many as twenty-one proposed systems submitted by various proponents. After a peer review process, the field was narrowed down to four systems. Proponents of these systems formed what would become known as the *Grand Alliance*: AT&T, General Instrument Corporation, Massachusetts Institute of Technology, Phillips Consumer Electronics, David Sarnoff

Table 1: ATSC Digital Standard A/53E Supported Formats

HDTV/SDTV	Horizontal lines	Vertical lines	Aspect ratio	Frame rate
SDTV	640	480	4:3	23.976p, 24p, 29.97p, 30p, 59.94p, 60p, 59.94i, 60i
SDTV	704	480	4:3 and 16:9	23.976p, 24p, 29.97p, 30p, 59.94p, 60p, 59.94i, 60i
HDTV	1280	720	16:9	23.976p, 24p, 29.97p, 30p, 59.94p, 60p
HDTV	1920	1080	16:9	23.976p, 24p, 29.97p, 30p, 59.94i, 60i, 60p

i = interlaced, p = progressive

Research Center, Thomson Consumer Electronics, and Zenith Electronics Corporation. The Grand Alliance built a working prototype of an HDTV terrestrial broadcasting system that used MPEG-2 compression. After a series of testing, the ATSC proposed DTV Standard A/53 that specified the protocol for high-definition broadcasting through a standard 6-MHz channel. DTV Standard A/52 outlined the use of digital audio through Dolby Digital, or AC-3, compression.

In December 1996, the FCC adopted most of the standards proposed by the ATSC, mandating that broadcasters begin broadcasting digitally. According to the ATSC, within one year of the November 1, 1998 rollout, more than 50 percent of the U.S. population was in a position to receive digital broadcasts. During a transitional period, television would be broadcast both digitally under the FCC's digital terrestrial television guidelines and through traditional analog means. Congress has voted to terminate analog broadcasting by February 2009, although the deadline could be extended.

DIGITAL TELEVISION, STANDARD DEFINITION TELEVISION, AND HIGH-DEFINITION TELEVISION

Although the NTSC standards defined one analog format, ATSC created a framework supporting several digital formats. The ATSC's DTV broadcasting standards provide for SDTV and HDTV programming using several possible frame rates. Because the technology is relatively new, there is a considerable amount of confusion among consumers regarding HDTV. DTV broadcasts can be either high definition or standard definition. SDTV can use either the 4:3 or 16:9 aspect ratios, but HDTV always uses the 16:9 aspect ratio (see Table 1).

Comparison to Standard Definition Television

Assuming an NTSC standard definition display of approximately 640×480 pixels, a 1080×1920 HDTV image has nearly seven times more pixels (see Figure 1). But in addition to the greater visual detail that the increased pixels provide, there are many other notable improvements that contribute to a heightened viewing experience. The delivery method of ATSC programming is considered to be an improvement over that of the NTSC. Analog television is susceptible to interference such as ghosting and

snow. DTV is digitally compressed; although not immune to all interference, such compression does eliminate a great deal of broadcast-related distortion. Because the signal is digital, the data either arrive perfectly intact or are noticeably absent.

Another improved element is audio. The ATSC standards call for AC-3, or Dolby Digital, sound; this can provide 5.1 surround sound as well as provide support for multiple audio bit streams. This allows broadcasters to deliver programming in multiple languages.

TECHNICAL ASPECTS

Codecs

Codec is short for both *compressor-decompressor* and *coder-decoder* and refers to a manner in which data are compressed and uncompressed. Compression can be achieved with software, hardware, or a combination of the two. In uncompressed form, a 1920×1080 HDTV signal requires nearly 1 Gigabyte per second (Gbps) of bandwidth. A *high-definition serial digital interface* (HD-SDI), specified by SMPTE 292M,* can carry high-definition video, as many as sixteen channels of embedded audio, and ancillary data at a nominal data rate of 1.485 Gbps. To squeeze the data into a form that can be reliably broadcast within a 6-MHz section of bandwidth, the signal must be compressed approximately at a 50:1 ratio. The ATSC DTV standard conforms to the main profile syntax of MPEG-2 compression standard.

As used in the current distribution of digital television, MPEG-2 uses *interframe* compression, which compresses both spatially and temporally. *Intraframe* codecs such as those for digital video (DV) treat each frame individually and thus only compress spatially. Because MPEG-2 can compress over time as well as space, it is capable of delivering a high-quality image in a smaller amount of bandwidth than an intraframe codec can deliver. A great deal of MPEG-2's efficiency is because it compresses the video into *groups of pictures* (GOPs) and not simply individual frames. In MPEG-2 compression, images are divided into *macroblocks*, which are typically areas of 16×16 pixels. The GOPs are created with three types of pictures: I, P, and B frames. *I frames* are intracoded frames, which are sometimes referred to as *index frames*. *P frames* are

* A standard developed by the Society of Motion Picture and Television Engineers.

Figure 1: Comparison of standard and high definition video formats (illustration courtesy of Tabletop Productions)

predicted frames, and *B frames* are bidirectional frames. A GOP starts with an I frame. In MPEG-2 compression, P frames are compared to the previous I or P frame. If there is a difference, a proper vector is determined to move the macroblock. If there is no change (if there is no movement within the shot), the bit rate can be reduced significantly. B frames work similarly but reference previous and future frames.

Some compression methods use intraframe compression, which treats every frame individually, compressing one after the next. These types of compressors such as M-JPEG or DV, facilitate editing because each frame is independent of the others and can be accessed at any point in the stream. Because MPEG-2 breaks the video stream into chunks known as GOPs, ease of editing is reduced in favor of maximizing compression. Although MPEG-2 is perhaps ideal for transmission, its multiframe GOP structure is not optimized for editing. It is possible to edit MPEG-2 without recompression as long as an edit point resides on a GOP boundary.

Metadata

DTV broadcasts with MPEG-2 also provide for *metadata* to be included along with the signal. Metadata are auxiliary information related to the program or its content and can include information such as audio dialog level data, closed captioning content, format descriptor tags, and *digital rights management* (DRM) data. Metadata can be processed at many stages along the delivery path.

Interlaced versus Progressive Scanning

An NTSC video signal is made up of 525 scan lines. On a CRT display, the image is created by an electron beam that excites phosphors on the face of the screen. The electron beam scans each row from left to right and then jumps back to draw the next line. The excited phosphors on CRT displays decay quickly after the electron beam makes its sweep. Because of the decay, images displayed at about 30 fps present a noticeable flicker. To reduce the flicker, the display frequency had to be increased. To achieve this, the frame was broken down into two fields. The first field displays only the odd lines, while the second displays only the even lines. So, instead of drawing approximately 30 fps, interlacing uses two fields, one after the next, at the rate of nearly 60 times a second.

Interlacing creates some unfortunate visible artifacts. Visual elements with fine horizontal lines will tend to flicker when displayed. In addition, capturing still frames or creating slow-motion effects shows temporal artifacts because the two fields have not been captured simultaneously, but 1/60th of 1 second apart. Other problems can occur when converting footage shot at 24 fps into 60-Hz interlaced fields.

By contrast, in progressively scanned video, the entire frame is captured all at once without two separate fields (see Figure 2).

Frame Rates

The ATSC standards bring new possible frame rates and also provide the ability to comply with existing,

Figure 2: Interlaced scanning. For illustrative purposes, the number of scan lines has been greatly reduced (illustration courtesy of Tabletop Productions)

traditional standards. Broadcast video under the NTSC standards employs an interlaced frame composed of two separate fields. As stated earlier, for technical reasons the refresh rate was reduced from 60 Hz to 59.94 Hz. In common terminology and documentation, sometimes the true 29.97 or 59.94 frame rates are used but often this figure is rounded up for the sake of convenience: 29.97 becomes 30 and 59.94 becomes 60. Because of this and the fact that the frame-numbering protocol used in time code is based on the rate of 30 fps, many people mistakenly think that the NTSC frame rate is a whole number. ATSC standards support both the NTSC 0.1-percent reduced frame rates as well as whole-integer frame rates of 24, 30, and 60.

Frame rate has a direct impact on the bandwidth required to carry a signal. A 60p signal would require approximately twice the bandwidth needed by a 60i signal.

One frame rate that is appealing to digital video cinematographers is 24p because it has been the standard film frame rate used by the motion picture industry for decades. This lessens the steps and expense required to transfer a copy to film for theatrical release and also helps the video look more like film.

Color Space

Computer-based digital imaging systems typically operate in an RGB color space or a variant of it. Broadcast video transmission, however, adopted a color difference model not only because the signal had to be compatible with existing black-and-white televisions but also because it had to take up as little bandwidth as possible. Most professional video cameras (both SDTV and HDTV) capture images into an RGB color space via three *charge-coupled devices* (CCDs). However, a growing number of cameras are using *complementary metal oxide semiconductor* (CMOS) sensors. Initially captured in uncompressed form, the RGB values are processed and converted into a color difference mode.

In the color difference system, the color signal can be numerically represented with three values: Y, B-Y, and R-Y. Mathematically, Y represents the value of the luma portion; B-Y and R-Y represent the two color difference values. The formulas used to derive the color difference values vary depending on the application. YIQ was the color-encoding system originally developed for NTSC while YUV was used for PAL. YPbPr uses a slightly different formula that is optimized for component analog video, while YCbCr uses a different scaling factor that is optimized for digital video.

Humans are more sensitive to spatial detail in brightness than in color information. Because of this, most of the important detail needed to comprehend an image is provided through the luma portion of the video signal. Engineers found they could throw out more than half of the color information and still get pleasing results. Compared to RGB, the Y, B-Y, R-Y scheme can store color data in a smaller amount of space and thus use less bandwidth when broadcast.

Color Sampling

Unless working in an uncompressed RGB mode, the color signal is converted into a color difference system. After

converting the RGB, the signal is sampled, quantized, compressed (usually), and then recorded to tape, hard drive, optical disk, or, in some cases, a memory card.

Color-sampling figures convey the manner in which the luma and color components are sampled for digitizing and are typically presented as a ratio with three figures: x:x:x. The first figure is usually “4” and refers to the number of luma samples. The second two figures correspond to the number of samples for the two color difference signals. For instance, DV’s 4:1:1 states that for every four luma samples, only one sample is taken for each of the color difference samples. A 4:2:2 format (such as DVC Pro50 or digital Betacam) means that for every four luma samples taken, two samples will be taken of each of the color difference signals. A 4:1:1 format would record half of the color information that a 4:2:2 format would. When a codec is represented by a 4:4:4, it is typically referring to an RGB signal.

The 4:2:0 color sampling format comes in a few different variants. As usually employed in MPEG-2, the color difference signals are sampled at half the rate of the luma samples but also reduced in half vertically.

Although formats using lower color-sampling ratios require less bandwidth, those with higher sampling ratios are preferred for professional editing, keying, and compositing.

Quantization

After sampling, the signal must be quantized—that is, assigned a numerical value. The number of quanta corresponds to bit depth. Video signals are usually captured into 8-bit or 10-bit per color channel formats. An 8-bit sample has 256 possible values, while a 10-bit sample has 1024 possible values. Generally speaking, a 10-bit sample will take more storage space but offer more contrast information.

Format Conversion

Because of the numerous types of media and formats in use, it is often necessary to convert from one type of format to another. *Transcoders* provide a means for doing so. Some can convert analog signals into digital (referred to as *A to D*) or digital into analog (*D to A*). Others provide a means to provide pulldown, de-interlacing, upconverting, and downconverting. *Upconverting* occurs when content is transferred to a superior format. *Downconverting* is copying to a format of lesser quality—for example, downconverting HD footage into SD footage. Sometimes it is necessary to manipulate the visual or pixel aspect ratio or change the image size (scaling). Other common transcoding tasks include changing the format temporally (vary the frame rate) and interlacing or de-interlacing the image. Bidirectional interfaces allow transfers from one format to another, such as from HD-SDI to analog component or SDI to HDMI.

Aspect Ratio Conversion

One benefit of HDTV is that its aspect ratio more closely matches that of widescreen film formats. Its 16:9 or 1.78:1 aspect ratio is close, but not quite as wide as the

Table 2 Common Aspect Ratios

Common Aspect Ratios	
Aspect Ratio	Application
4:3 or 1.33:1	Traditional television and 16 mm and 35 mm film
1.37:1	Academy aperture
16:9 or 1.78:1	Widescreen television
1.85:1	Standard theatrical widescreen
2.20:1	70mm
2.40:1	CinemaScope

popular 35-mm anamorphic widescreen (see Table 2 and Figure 3). Some may argue that the widescreen format is at a disadvantage for playing old movies such as *The Wizard of Oz* or *Gone with the Wind*, but in general

widescreen formats have become more favored for film since the 1950s.

Although HDTV content is designed to fill a 16:9 frame, the display of programming from other sources with varying aspect ratios is also possible. Programs shot in the 4:3 aspect ratio or in wider cinematic formats can easily be displayed inside a 16:9 frame without distortion by shrinking the image. Unfortunately, it is quite common to see broadcasters delivering images with the improper aspect ratio (example A of Figure 4). Traditional 4:3 content is ideally viewed on widescreen displays by presenting the image as large as possible and centered within the frame (example B). This is sometimes referred to as *pillar boxing*. This allows the original image to be seen as it was intended. Some broadcasters magnify the 4:3 image so that it fills the entire 16:9 frame (example C). This can often be identified by the lack of headroom. Content from cinematic formats with wider aspect ratios can be accurately displayed within the 16:9 frame with *letterboxing* (example D). It is also frequently necessary

Figure 3: Common aspect ratios (illustration courtesy of Tabletop Productions)

Example A 4:3 content improperly displayed within a 16:9 frame. The image has been stretched to fill the entire frame.

Example B 4:3 content properly displayed in the center of the 16:9 frame.

Example C 4:3 content scaled up in order to fill the entire 16:9 frame.

Example D Content from a 70mm film with a 2.20:1 aspect ratio letterboxed within the 16:9 frame.

Figure 4: Content with varying aspect ratios displayed within a 16:9 frame (images courtesy of Table top Productions)

to present widescreen programming inside of traditional 4:3 displays with letterboxing.

The ATSC standard supports an *active format descriptor* (AFD) data tag that can be embedded into the encoded video. The AFD data tag describes the aspect ratio of the signal when it does not extend to the edges of the frame. If utilized, the receiver or set top box can decode the AFD data tag and display the signal with the proper aspect ratio.

The 3-2 Pulldown

A common frame conversion task is required by the frequent need to change 24p content into 60i. Such is the case when converting film (which runs at 24 fps) into 60i. This 3-2 *pull-down*, sometimes called the *telecine process*, is also required when changing 24p video into 60i. Some systems employ a 2-3 pull-down; although reversing the order, this achieves the same end result.

The basic idea between the 3-2 pull-down is that four frames of 24p footage are converted into five interlaced video frames. It is called 3-2 (or 2-3) because each consecutive 24p frame is transferred into two fields followed by three fields, then two fields, and so on. One step is to slow the film down by 0.1 percent to the rate of 23.976 frames per second. In Figure 5, we have four frames of 24p material, labeled A, B, C, and D. The first video frame contains two fields of frame A. The second video frame contains one field of A and the second field of B. The third video frame contains one field of B and one of C. The fourth video frame contains two frames of C. The fifth video frame contains two fields of D.

IMPLEMENTATION

The HDTV production chain typically begins with a high-definition camera or a project shot on film that is then converted to a digital format. However, other means are possible. Much of director Tim Burton's recent stop-motion feature film *The Corpse Bride* was shot with a

Canon digital still camera and then transferred to digital video for editing. Many commercials, cartoons, and full-length features have been created solely with two-dimensional or three-dimensional animation software.

Cameras

HDTV cameras were used long before the ATSC standards were in place. Because of the move to DTV and the growing acceptance of HDTV by consumers, many broadcasters are choosing to replace retired or existing standard definition equipment with high-definition camera gear. Although higher-end production cameras suitable for studio or digital cinematography can cost more than \$200,000 apiece, many professional HD camcorders used for daily production tasks can be found between \$20,000 and \$60,000. Recently, a few companies have released HDTV camcorders priced less than \$1500 targeted to consumers. Generally speaking, camcorders with high-quality lenses that are capable of writing higher data rates and recording images up to 1920×1080 pixels in varying frame rates occupy the higher end of the price range. Camcorders with lower-quality optics that use lower data rates, GOP-based compression, and have fewer frame rate options can be found at the lower end of the price range.

Recording and Playback Formats

Recording, storage, and playback of HDTV content can be done in several ways. As in standard definition digital video, the data can be written to tape, hard drive, optical disk, or random access memory (RAM). The following are some of the more popular formats currently used for high-definition video production. (Refer to Table 3 for side-by-side comparisons.)

D-VHS

The D-VHS consumer format from JVC records onto VHS tapes using an MPEG-2 stream at as high as a 28.2-Mbps data rate. It is backward-compatible with VHS appealing

Figure 5: The 3-2 pulldown (illustration courtesy Tabletop Productions)

Table 3: Comparison of HD Field and Production Formats

Name	Format	Pixel dimensions (recorded)	Color sampling	Bit depth	Compression	Data rate	Audio channels
HDV	1080 60i	1440 × 1080	4:2:0	8	MPEG-2	25 Mbps	2
	1080 50i						
	720 60p	1280 × 720	4:2:0	8	MPEG-2	19.7 Mbps	2
	720 50p						
	720 30p						
XDCAM HD	720 24p						
	1080 60i	1440 × 1080	4:2:0	8	MPEG-2	Adjustable: 18 Mbps 25 Mbps 35 Mbps	4
	1080 50i						
	1080 30p						
	1080 25p						
D9-HD	1080 24p						
	1080 60i	1280 × 1080	4:2:2	8	DCT	100 Mbps	8
	720 24p	960 × 720					
	1080 60i	1280 × 1080	4:2:2	8	DCT	100 Mbps	8
	1080 50i	1440 × 1080					
DVCPRO HD (D12)	720 60p	960 × 720					
	720 50p						
	1080 60i	1280 × 1080	4:2:2	8	DCT	235 Mbps	8
	1080 30p	1280 × 720		10			
	1080 24p						
D5 HD	720 60p						
	1080 60i	1920 × 1080	4:2:2	8	DCT	140 Mbps	4
	1080 30p	1280 × 720					
	1080 24p						
	720 60p						
HDCAM (D11)	1080 60i	1440 × 1080	3:1:1	8	DCT	140 Mbps	4
	1080 50i						
	1080 25p						
	1080 24p						
	720 60p						
HDCAM SR	1080i 60	1920 × 1080	4:2:2 at 440 Mbps	10	MPEG-4	440 Mbps	12
	1080i 50		4:4:4 at 880 Mbps				
	1080PsF 30						
	1080PsF 29.97						
	1080PsF 25						
	1080PsF 24						
	1080PsF 23.98						
	720p						

to consumers with sizable VHS tape collections. It is not considered a viable commercial production format.

HDV

Canon, Sony, and JVC offer lower cost HDV cameras that record at a maximum resolution of 1440×1080 . HDV uses a form of MPEG-2 compression that can be recorded onto mini-DV cassettes. In 1080i mode, HDV can record a 25-Mbps signal. In 720p mode, it records at 19Mbps. Because MPEG-2 employs GOPs instead of discrete frames, HDV data is often upconverted into a different format for editing. Because the data rate is relatively low, HDV content can easily be transferred over a FireWire (IEEE-1394) connection.

DVCPRO HD

Also known as D12, DVCPRO HD was developed by Panasonic and has versions that record on magnetic tape as well as to memory cards. The 100-Mbps data rate is still low enough to be transferred over a FireWire connection from a videotape recorder into an editing system. DVCPRO HD is restricted to a maximum resolution of 1280×1080 pixels.

XDCAM HD

Sony's tapeless XDCAM HD format records onto Blu-Ray optical disks using several possible frame rates and codecs. It can record HD content using MPEG-2 encoding at 35Mbps or DVCAM at 25Mbps. Its HD resolution is restricted to 1440×1080 pixels.

D-5 HD

Developed by Panasonic in 1991, the D-5 format has been updated to HD. It records at a 235-Mbps data rate and can handle 720 and 1080 content at most possible frame rates.

HDCAM

Sony's HDCAM format records onto 1/2-inch videocassettes at several possible frame rates. It uses a 140-Mbps data rate and supports as many as four channels of audio. It, too, is restricted to a maximum resolution of 1440×1080 pixels.

HDCAM SR

Sony's higher end version of HDCAM shares some of the same features but can write data rates as high as 880 Mbps with as many as twelve audio channels.

Editing

Although linear, tape-to-tape editing is still viable (and sometimes best suited for the job), most editors work with computer-based, nonlinear editing systems. With dozens of vendors making HD-capable editing systems, many codecs are available. Some require proprietary hardware to use, while others are hardware-independent. In addition to the standard 8- and 10-bit depths, there are also higher-end, 16-bit codecs available from companies such as Pinnacle and Digital Anarchy.

Although HDTV is routinely compressed using MPEG-2 for transmission and delivery, uncompressed or mildly

compressed data are preferred for editing. Because it is often necessary for editors to composite many layers of content together in order to create special effects, the signal must be kept as pristine as possible. This is why editors will often upconvert footage to a codec with better bit depth and higher resolution.

Video Capture

HDTV data may be brought into a computer through FireWire, HD-SDI, or digital or analog component capture. Footage can be transferred into an editing system bit for bit, or it can be encoded into a codec that is more suitable for editing. A detailed discussion of HD editing codecs is outside the scope of this chapter, but color space, bit depth, and compression are three factors that should be considered along with the overall format and frame rate. In addition, certain broadcast channels or clients have precise technical requirements that may affect the choice of codecs. As mentioned previously, 10-bit files contain more information than 8-bit files but also require more storage. Projects with demanding chroma-keying or color-compositing needs will be better served by codes with higher color sampling ratios (4:2:2 over 4:1:1, etc.). Similarly, compressed footage requires less bandwidth at the trade-off of some quality loss. Lastly, choosing a lossless codec that operates in a 4:4:4 resolution will offer the highest quality but at the expense of requiring the greatest amount of storage.

Video Storage, Servers, and Networks

In uncompressed form, HDTV content requires more disk space than standard definition video and a larger bandwidth to access or deliver media. Consider this comparison. An hour of standard definition DV footage with a stereo pair of 16-bit audio tracks captured at 25Mbps takes approximately 14Gb of disk space. An hour of 10-bit 1920×1080 HD footage with a pair of 24-bit audio channels requires nearly 600Gb of space. The same footage captured in RGB uncompressed would fill almost 900Gb.

Video editing, production, and broadcast delivery systems often require several streams of video to be accessed simultaneously. As well as providing access to multiple users, HDTV data must be safeguarded in some way. A common approach to this utilizes network-based storage architecture. Typical systems incorporate a video server that allows for multiple connections and interfaces with a *redundant array of independent disks* (RAID) storage device. Although HD content can be stored and retrieved over standard or Fast Ethernet connections, the high bandwidth and constant throughput required to deliver HD in professional applications requires the use of fibre channel or 10-Gigabit Ethernet. Architecture for storage systems will likely be based on a *storage area network* (SAN) or *network attached storage* (NAS). Either way, they will likely rely on RAID storage. RAIDs use multiple hard drives in a single enclosure that are written to and read simultaneously. Common RAIDs used for HD storage are the following:

- RAID 0 stripes the data across two or more disks. No parity information for redundancy is recorded, so there

is no protection offered against data loss. If one drive goes out, all of the data are lost.

- RAID 3 uses at least three or more drives. Parity information is recorded on one of the disks while the data are striped evenly across the other drives. RAID 3 arrays can be backed up with relative ease if one of the drives goes bad.
- RAID 5 contains three or more drives per set. Parity information is stored on all of the drives equally. RAID 5 sets can generally handle data transfers more quickly than can RAID 3.
- RAID 50 (5 + 0) uses two or more RAID 5 sets striped together into a single RAID 0. Each RAID 5 element typically is on an individual controller. RAID 50 provides an excellent mix of fast read and write speeds and redundancy.

Display Technologies

HDTV content can be viewed using several different technologies including the aforementioned CRT, *liquid crystal display* (LCD), plasma, *digital light processing* (DLP), and *liquid crystal on silicon* (LCoS). Displays can be “direct view” with the image generated on the screen’s surface or projected from the front or rear. Each technology has its strengths and weaknesses. Although some experts argue that traditional CRT displays are the best means to accurately monitor color, their vacuum tube construction ultimately renders them unsuitable for large, widescreen displays. Because of their limitations, other microdisplay technologies such as LCD, plasma, DLP, and LCoS have gained favor in both consumer and professional markets. In addition to these, there are other viable HDTV display technologies including *organic light-emitting diode*, *grating light valve*, *nano-emissive*, and *surface-conductive electron emitter* displays.

Besides pixel resolution, important factors to consider when comparing different displays include contrast, brightness, and color. In addition, how well the displays scale and de-interlace images is significant. These factors ultimately determine why some displays look better than others or are more suitable for a particular installation or location.

CRT

CRT monitors draw the lines one after the next, from top to bottom, to make an entire frame. Generally speaking, they have pleasing color balance performance and wide viewing angles. Because of their use of vacuum tubes, the displays cannot be constructed much larger than 40 inches or so. They weigh more than the other types of displays, use a significant amount of power, and generate heat. Rear-projection monitors typically use three CRTs (red, green, and blue) that converge onto a projection screen. Rear-projection CRT displays have good colors and black levels, but they are heavy, take up sizable amounts of room, and suffer from low output and limited viewing angles. Front-projection systems offer excellent resolution and are still favored by many people but are large and require periodic maintenance to ensure proper convergence and focus.

LCD

LCD HDTV monitors work by casting light through an array of cells sandwiched between two polarized planes. LCD monitors come in both flat-panel and rear-projection varieties. Flat-panel, direct-view monitors have become popular as computer and DTV monitors because of their brightness, high contrast, and relatively long life span. Traditionally, LCDs have had a slower response time and lessened viewing angles than their CRT counterparts, but their speed and angle of view have been improved in recent years. Unlike plasma monitors, LCDs do not suffer from *burn-in* damage that results when a static or constantly illuminated image area begins to dim over time.

Plasma

Like LCD monitors, plasma HDTV sets are thin and are made of cells that correspond to pixels sandwiched between glass plates. Plasma cells contain three separate gas-filled subcells, one for each color. When a current is applied to a subcell, it ionizes the gas-emitting ultraviolet light. The ultraviolet light in turn excites fluorescent substances in the subcells that emit red, blue, or green light. Compared to LCD, plasma sets can cost more but have larger viewing angles. Although they also can suffer from low-level noise in dark material, in general they have deeper blacks. Some older plasma sets suffered from burn-in and limited life spans, but these have been improved in recent years.

DLP

Digital light processing is a technology used in projection displays. In DLP monitors, light is reflected off an array of microscopic hinged mirrors. Each tiny mirror corresponds to a visible pixel. The light is channeled through a lens onto the surface of the screen. Single-chip DLP projectors can display 16.7 million colors. Although some manufacturers claim their three-chip DLP projectors can display 35 trillion colors, critics have observed that humans are only capable of discerning some 10 million.

LCoS

LCoS projection systems use liquid crystals arranged in a grid in front of a highly reflective silicon layer. The liquid crystals open and close, either allowing light to be either reflected or blocked.

Cables and Connectors

With the large and growing number of cameras, displays, recorders, and playback devices for both professional and consumer markets, numerous connection options are available. HDTV production equipment typically features digital inputs and outputs, along with legacy analog formats for both monitoring and additional I/O flexibility. Because HDTV content is digital data that are routinely stored, delivered, and processed over networked systems, standard computer connectivity such as Ethernet, WiFi, and USB can be used. Note, however, that the limited bandwidth of these connections might not support real-time delivery. In addition to the aforementioned computer connections, the following connectors are commonly used in HDTV equipment.

HD-SDI

A SMPTE 292-Mb serial digital interface (HD-SDI) connection provides for transfers up to 1.485 Gbps over a 75-ohm coaxial cable. This is a standard method of transferring an HDTV signal from one device to another, such as from a digital recorder to an editing system. As many as sixteen channels of digital audio can be delivered along with the video.

IEEE-1394: FireWire or i.Link

Created as a versatile multimedia serial bus, IEEE-1394, commonly referred to by Apple as FireWire and by Sony as i.Link, allows bidirectional connectivity between a growing number of computers and multimedia devices. Two variations of FireWire support either 400 Mbps or 800 Mbps.

Component

Both analog and digital color difference connectors can be found on HDTV equipment. In the case of digital connections, YCbCr is used. Analog uses YPbPr, with audio being handled through a separate connection.

HDMI

A *high-definition multimedia interface* (HDMI) connection can carry both multichannel audio and video through one cable. It is found on some satellite and cable boxes along with a growing number of consumer and semi-professional gear.

DVI

Digital video interface (DVI) connections are commonly found connecting computers and flat-panel displays. DVIs can be connected to HDMI with an adaptor. There are three types of DVI interfaces: (1) DVI-A contains only analog connections, (2) DVI-D only digital, and (3) DVI-I supports both analog and digital.

DisplayPort

This new display interface is physically smaller than a DVI connector and supports resolutions up to 2048×1536 pixels at 30 bits per pixel. It is designed to replace DVI and LVDS connectors and can be used for both external and internal display connections.

UDI

The *unified display interface* (UDI) is another new interface for PCs and consumer electronic devices designed to replace the VGA standard. It is designed to be compatible with HDMI and DVI interfaces, delivering high-definition video and metadata through a single connector.

Broadcast Transmission and Reception

Overall, the traditional model of broadcast transmission over the radiofrequency spectrum is unchanged. However, DTV requires broadcasters to replace analog with digital transmission gear and consumers to upgrade to digital receivers. The new technologies and digital infrastructure are providing broadcasters with new options such as multicasting. Within a single 6-MHz section

of bandwidth, a broadcaster can deliver a 1080i HDTV broadcast, offer multiple audio and video streams along with a variety of data, or both.

Reception

HDTV programming can be received via traditional terrestrial broadcast, cable, satellite, or even Internet protocol television (IPTV). To receive HDTV programming (via DTV broadcast), end users need a receiver with an ATSC-compliant tuner. Cable and satellite companies currently provide set-top tuners and demodulators. Some contain *personal video recorders* (PVRs) that are capable of recording and playing back both standard and high-definition content. Many new HDTV sets referred to as “plug and play” or “digital cable ready” can interface with the digital service providers by means of a security card (known as a *cableCARD*), which is a small card with integrated circuits that plugs into the back of the console. Interfacing with the broadcast service providers through some form of return channel is necessary in order to use services such as *pay-per-view* (PPV), *video on demand* (VOD), or, in some cases, interactive programming.

Terrestrial

This traditional over-the-air system of transmission uses radio frequencies allocated by the FCC. TV stations broadcast from a single point, or through ancillary translators or repeaters that rebroadcast the originating signal, to end users who are physically located within the station's receiving area. Reception of terrestrially broadcast DTV requires an antenna and limits the reception to those located within a TV station's service area. Although new sets are being manufactured with DTV-compatible tuners, stand-alone set-top devices will be available so that existing analog televisions can still be used. It should be noted that existing antennas would work fine for DTV broadcasts.

Cable

Cable service providers retransmit programming to end users over coaxial or optical cable. One main benefit of digital cable is the ability to offer a wide variety of programming as well as provide a broadband Internet connection. Two-way digital cable is uniquely structured, providing a built-in return channel facilitating the use of PPV, VOD, and interactive programming.

Satellite

Direct broadcast satellite (DBS) service transmits digitally compressed programming to users via small, K_u band antennas. Like cable, satellite service providers retransmit existing content and offer a variety of programming packages.

Internet Protocol Television

Interest and development is growing rapidly in IPTV, which provides DTV service over a broadband connection. Wire-service broadband providers, such as telephone companies, who have not traditionally been vested in television, seem to have the most interest in developing

the technology. There is also growing interest in providing IPTV use over standard 802.11g wireless networks.

Usage and Saturation

A recent survey carried out by Panasonic in December 2005 (Broadcast Newsroom 2005) reported that 26 percent of U.S. households would own or would have purchased a high-definition set by the end of 2006. Given the imminent demise of analog broadcasting and the growth of HDTV content, it is safe to assume that figure will continue to grow.

The National Association of Broadcasters (NAB) maintains a growing list of stations that have made the move to digital broadcast. In December 2005, 1550 stations were broadcasting digitally. As of January 2006, the major commercial broadcasting networks (ABC, CBS, FOX, and NBC) had begun to offer most of their prime time programming in HD form. The Discovery Channel runs 24-hour HDTV programming, and PBS HD was expanding its schedule as well. Major satellite and cable service providers DirecTV, Dish Network, Comcast, and Insight all offer an increasing lineup of HDTV programming along with time-shifting PVRs.

IMPACT OF HIGH-DEFINITION TELEVISION

Users

According to studies, HDTV results in a heightened sense of “presence” (Bracken 2005) in viewers—that is, the viewer has a sense of being *in* the televised environment. Another aspect of presence is the degree to which the technological medium is ignored as attention becomes focused on the content. Because HDTV delivers an increased viewing experience, it is also suggested that levels of media effects will rise as well. The primary factors leading to the increased feeling of presence include screen size and image quality. Bracken’s research found that subjects viewing HDTV content felt an increased feeling of immersion or involvement in the material. Participants also reported feeling a greater spatial presence of objects as well as an increased sense of the televised characters’ expressions and body language.

Television Production

HDTV’s wider aspect ratio and more detailed image are two elements that affect production. Sets, graphics, and other production elements that may have served well for the 4:3 aspect ratio needed to be redesigned to fill the wider space. The increased visual clarity has forced designers to spend considerably more money on sets, set dressings, and props. With the old analog system, fake, painted-on books might have served well for a bookshelf backdrop, but now viewers can see more detail so real books, or at least better paint jobs, are needed. There has been some press about the need for TV actors to invest in cosmetic surgery, or at least spend more time in makeup, because of the greater detail HDTV provides. This is mostly a myth. The likenesses of film talent have been displayed at a much greater size and with far more

clarity on large movie screens for years. By using soft lights and decreasing the angle of key lights, lighting designers can greatly reduce the appearance of wrinkles and imperfections. Contrast reduction filters also can help minimize blemishes and small shadows.

Digital Video Discs

High-definition DVD manufacturers are currently engaged in a format war, with the major contenders being Blu-Ray and HD-DVD. Both formats have considerable industry backing. The formats are similar in using the familiar 120-mm diameter CD-sized discs, but they use higher-frequency 405-nm wavelength lasers that are capable of writing and reading data more tightly together. Players of both formats are being made that are capable of reading existing analog DVDs.

Blu-Ray Discs

Single-layer Blu-Ray discs can hold approximately 25 Gb, and dual-layer discs can hold some 50 Gb writing MPEG video at data rates as high as 36 Mbps. Although the Blu-Ray lasers are not directly compatible with existing DVDs and CDs, an additional optical pickup device achieves playback.

High-Definition DVDs

The DVD Forum, an industry group whose purpose is to establish technical standards for DVD technology has sided with the HD-DVD format. Although HD-DVD players write with the same 36 Mbps rate as the Blu-Ray format, a single-sided disc can only hold 15 Gb and a dual layer disc approximately 30 Gb.

Feature Films

The era of digital cinema began when George Lucas released *The Phantom Menace* digitally to select theatres on June 18, 1999. Digital cinema replaces traditional film distribution and projection with digital delivery and projection. Digital cinema may use high-definition technology, but it is not directly tied to ATSC’s DTV standards. The formats currently used in digital cinema provide even higher resolution than HDTV, including 2K (2048 × 1080) and 4K (4096 × 2160). Much of the equipment and interconnections used for HDTV production also work with digital cinema formats.

Using digital cameras to shoot a motion picture project is referred to as *digital cinematography*. Some filmmakers have resources to shoot with larger, ultrahigh definition cameras such as Panavision’s Genesis, but most are opting to shoot in HDTV or with even smaller, standard-definition formats because of the mobility, ease of editing, and low cost. Digital cinematography provides filmmakers with a means to shoot, edit, and master a project in the digital realm. With digital cinema, they now have a direct path into theatrical distribution. Although some film production companies view HDTV and digital cinema as a threat, many studios are major proponents who see it as a way to reduce the costly expense of duplication and distribution. A single 35-mm film print can cost more than \$1500

to produce. Other benefits include the fact that there is no loss of quality after multiple viewings and that more advertising can be run and edited more quickly and efficiently.

The 1999 *Phantom Menace* screenings used media and projectors that were only capable of producing 1280×1080 sized images, but current installations are using more advanced technology. The latest digital projectors are capable of displaying images with pixel dimensions of 4096×2160 . Christie, a leading manufacturer of high-definition projectors for the digital cinema market, has agreements to install 2300 projection systems by November 2007.

CONCLUSION

As analog broadcast retires, and as broadcasters and viewers transition to DTV, HDTV programming, products, and services will continue to grow exponentially. Although both broadcasters and consumers may have experienced a few bumps as they have transitioned to DTV, the move will come more cheaply, more quickly, and more easily as products and services become more widespread and people grow accustomed to the new technology.

Savvy shoppers have already become familiar with HDTV along with the nuances of different displays and formats. According to the Consumer Electronics Association, in 2003, total dollar sales figures of HDTV sets surpassed those of analog sets. The purchasing process for uninformed consumers has been made easier by the FCC, which has required that manufacturers include ATSC-compatible digital tuners in their TVs. The FCC also has established a standard for *digital cable ready* (DCR) televisions, known as “plug and play.” This allows cable subscribers to receive digital and high-definition programming without the need for a set-top box.

One interesting phenomenon is that despite advances and increased availability in HDTV gear and service, the demand for low-definition video has also increased. Although some consumers might watch the latest episode of *Lost* or *Desperate Housewives* on large HDTV sets, a growing number are downloading 320×240 sized versions onto their iPods and portable digital media players.

HDTV has brought a more cinematic experience into viewers' homes and, with digital cinema, delivered the film industry a few of the benefits of television. However, HDTV has much lower resolution than 70-mm film. It is only a matter of time before some will begin pressuring for another increase in quality.

GLOSSARY

Aspect ratio: A ratio of screen width compared to height.

Bandwidth: The amount of data that can be sent through a signal path.

Digital TV (DTV): A standardized system of transmission and reception of digital television over radio frequencies.

Downconvert: Converting a higher-resolution format into a lesser-resolution format.

High-definition TV (HDTV): A high level of DTV that is capable of displaying 720p or 1080i television content using a 16×9 aspect ratio.

Interlace scan: A technique used in NTSC broadcasts in which a television image is created with two separate fields.

Letterboxing: The effect of an image presented in a display with a narrower aspect ratio. When this occurs, horizontal black bars are visible at the top and bottom of the screen.

Metadata: In the digital television context, refers to data about the programming such as start and stop times, titles, and information on the following show.

MPEG-2: A version of the MPEG video file format used to deliver digital video (from *Moving Picture Experts Group*).

Multicast: When a broadcaster splits its bandwidth into separate channels or program streams.

Personal video recorder (PVR): A digital recorder that allows a user to record, store, and playback video such as television broadcasts from a hard drive.

Progressive scanning: Method of scanning all of the scan lines from top to bottom sequentially without two interlaced fields.

Standard definition TV (SDTV): The lowest quality level of DTV that is capable of displaying 480i television content.

Upconvert: Converting a lower-resolution format into a higher-resolution format.

Widescreen: Term that describes displays with an aspect ratio greater than 4:3.

INTRODUCTION

Few would disagree that the emergence of tele- and data-communication technologies—specifically, the ability to both transmit and receive voice, video, and data—has had profound impacts on both our personal and professional lives. Although many have contributed to the progression of modern-day communication networks, the works of Samuel Morse and Alexander Graham Bell (i.e., Morse code and the telephone network, respectively) provide the foundation for much of the last mile, or local loop, communication infrastructure in use today. In other words, the same basic physical circuitry between residential homes and a telephone company's central or end office remains unchanged. Thus, even in today's technology-driven economy, consumer-based, network-capable technologies (e.g., computers, video games), although digital in nature, continue to utilize, at least in the last mile, both guided and wireless analog-based circuitry (e.g., dialup, cable, wireless). As such, translational protocols and devices are necessary.

In this chapter, we discuss one such device: the modem. Modems first emerged as a communication solution to the binary-analog dichotomy that existed between computer data and existing voice-grade circuits. Specifically, computers produce binary or discrete data (e.g., 1's and 0's), whereas the existing telephone circuitry and hardware are designed to transmit analog data—that is, data that are continuous in nature and constantly varying. Essentially, to transmit discrete data over voice-grade circuits, digital data must be *modulated* or converted to analog signals. Similarly, the receiving computer requires that all incoming analog signals be *demodulated*—that is, converted back to binary data. As such, the term *modem* emerged as a contraction of these two primary functions—modulation and demodulation—and traditionally has been defined as any physical, networking device that allows computers, or other binary-based

technologies, to transmit data over standard telephone or plain old telephone service (POTS) lines.

With the proliferation of the Internet and World Wide Web, the definition of modems, like many other networking technologies, has evolved. For example, Horak (2002, p.182) writes, “Modems modulate and demodulate signals. In other words, they change the characteristics of the signal in some way.” From this definition, the term *modem* subsumes any device that meaningfully modifies data for the purposes of transmission. In this chapter, the traditional definition is used to refer to dialup modems, while Horak's definition is used to accommodate broadband modems (e.g., cable, DSL, and wireless).

The chapter begins by providing a brief historical perspective. This is followed by a high-level discussion of how dialup modems work. We then classify modems on several salient dimensions: their architecture, locality, mode of transmission, and synchronization. Following this, modem protocols, or standards, are discussed and presented (e.g., data flow, data rate, compression, and error checking). Subsequently, we present and summarize what we term here as *next-generation modems* (e.g., wireless, cable, optical). Finally, last mile connectivity technologies and trends are discussed.

HISTORICAL PERSPECTIVE

In this section, we present a succinct history of modems. For a comprehensive historical review, see AT&T (undated “Milestones,” undated “History”), Green (2000), and Horak (2002).

Modems were first introduced and used in the government sector in the 1950s, specifically as a data transmission solution for the North American Air Defense Command (NORAD). Mainstream commercial usage of modems began with AT&T's introduction of the Bell 103 in 1962. Initially, modems were primarily used for connecting remote terminals to servers and mainframes.

Until the mid-1980s, modem speeds (signals per second or baud) and data rates (bits per second or bps) made little progress (300 to 1200 bps). This slow advancement was principally because of the dominant host-based application architecture and lack of standards. In other words, other than the presentation logic, the server or mainframe performed all primary application functions (e.g., data storage, data access, application logic). However, as application architectures evolved (e.g., client-based and client server-based), and as standardization became a central theme, data rates advanced more quickly.

By the mid-1980s, many of the signaling, fallback, error-detection and -correction, and standardization hurdles were overcome (these, and many of the other terms used herein, are defined in the glossary or discussed in greater detail in the sections that follow). During this same time period, new modulation (e.g., amplitude, frequency, and phase) and echo cancellation techniques were also being successfully employed. As a result, data transmission speeds of 9600 bps became commonplace.

The 1990s were a time of great advancement. As the Internet and World Wide Web continued to proliferate, engineers began experimenting with ways to increase modem speeds beyond the limits of purely analog-based modems (e.g., V.34+). By this time, with the exception of the local loop, virtually all of the telephone circuitry in the *public switched telephone network* (PSTN) was digital. It was thus reasoned that if the transmission remained digital between central or end offices, the data throughput rates could be dramatically increased. In other words, it would meaningfully reduce the number of digital-to-analog conversions and, as a result, reduce the amount of data that would be compromised or lost during each conversion (a bit of data is compromised or lost during each digital-to-analog conversion). From this logic, the V.90 and V.92 standards were born, and data rates went from 14,400 bps in early 1990 to 56,000 bps by the end of the decade.

These advancements, like earlier modem technologies, were immediately embraced by the International Telecommunications Union (ITU), and became the recognized international standard (V.90 and later V.92) by the turn of the century. It is believed that the V.92 standard, or 56K(Kbps), is the maximum—or, at the very least,

the penultimate—data rate possible for dialup modems given the dedicated bandwidth (4000Hz) and Federal Communications Commission (FCC) power limitations of voice-grade circuits on the local loop, which limit the maximum download transmission rate to 53 Kbps.

In the next section, we discuss dialup modem components and their functionality.

MODEM FUNCTIONALITY

In the most general sense, modems are used to modify binary or digital data in some way that affords transmission over guided (e.g., twisted-pair, coax) or wireless (e.g., radio, infrared, microwave) media. Although transparent to the network user, traditional dialup modems automatically dial and redial, monitor call progress, negotiate and agree on protocols and features (known as the “handshake”), and terminate calls. Figure 1 illustrates the process of modulating and transmitting digital data with a dialup modem via the analog local loop and digital PSTN. What follows is a discussion of the V.92 dialup modem standard, as well as its key features and components.

The V.90/92 standards became the first *hybrid*, or analog-digital, modems. Essentially, V.90/92 series modems increased data rates beyond purely analog modems (e.g., V.34+) through the use of *pulse code modulation* (PCM), specifically by inverting the codec process. The term *codec* derives from a contraction of the device’s two primary functions: to code and to decode (that is, a codec at each central or end office is employed to digitize analog voice signals as well as decode digitized voice signals back into their analog counterparts for the purpose of transmitting voice data over the PSTN). Instead of sampling analog voice signals 8000 times per second via one of 256 quantizing levels (the number of levels deemed necessary to digitize the human voice without degradation), V.90/92 modems are engineered to recognize 8-bit digital symbols (any of the 256 possible amplitudes, or sample heights, used in PCM) 8000 times per second.

As such, current V.92 modems are designed to provide downstream speeds as high as 56 Kbps—that is, $(8 \text{ bits} - 1 \text{ control bit}) \times (8000 \text{ samples per second}) = 56 \text{ Kbps}$ —and upstream speeds as high as 48 Kbps. Note, however, that actual transmission speeds are limited by both regulatory

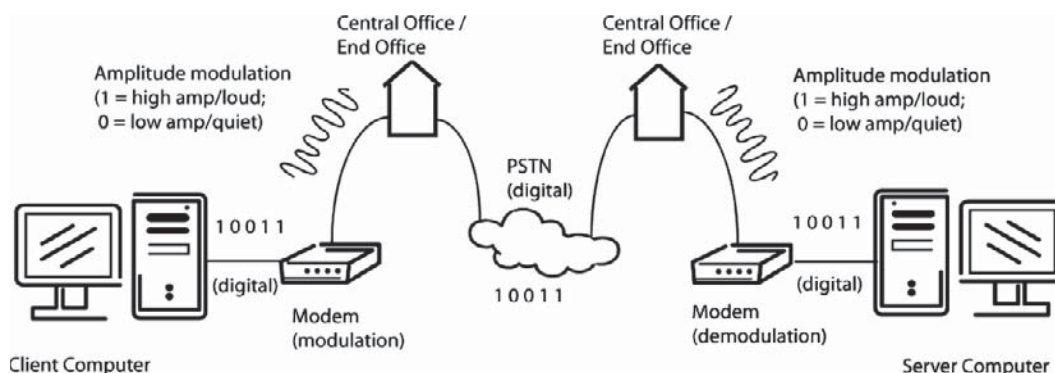

Figure 1: Modem example

conditions (e.g., the FCC in North America) and circuit conditions (the latter is discussed to a greater extent in the section titled “Modem Standards”). As such, transmission speeds rarely if ever reach these theoretical transmission rates. In addition to reversing the codec process, the V.92 standard also supports many new features such as quick connect, modem on hold, PCM upstream, and V.44 data compression. The *quick connect* feature reduces the initial handshake time from 30 seconds to 10 to 20 seconds. The *modem-on-hold* feature allows users to accept incoming voice calls without compromising or releasing their data connection. *PCM upstream* affords both the transmitter and receiver the option to receive PCM schemes so that data transmission speeds can, in theory, reach data rates as high as 56 Kbps. We now turn to a discussion on the inner components of a traditional dialup modem.

In general, dialup modems have three primary components: a *microcontroller unit* (MCU), a *data pump unit* (DPU), and a *data access arrangement* (DAA).

Microcontroller Unit

The MCU has four primary functions: (1) to check for errors in the data (V.42), (2) to compress the data (V.44), (3) to provide fax capabilities, and (4) to convert parallel transmissions into serial transmissions when needed. If the modem is Hayes-compatible (see Wikipedia 2006 “Hayes”), then the MCU utilizes the Hayes AT command set to control the modem—that is, to send and receive data. When the MCU finishes processing, it transfers data to the DPU.

Data Pump Unit

The *data pump unit* (DPU) has three key parts: *random access memory* (RAM); *read-only memory* (ROM), or *electrically erasable programmable ROM* (EEPROM); and a *digital signal processor* (DSP). The DPU receives initial instructions from ROM, and it uses RAM for temporary storage during calculations. The DPU is responsible for modulation and echo cancellation—that is, it is responsible

for converting the binary data to analog data. When the DPU finishes processing, the data are sent to the DAA.

Data Access Arrangement

The *data access arrangement* (DAA) is the modem’s physical interface to POTS lines. Essentially, it is a female, voice-grade, RJ-11 telephone jack.

The process described above is based on a transmission sequence. Note that the receiving sequence or process, in general, would be in reverse order; and that some of the component functionalities (e.g., MCU) also would be reversed—that is, decompressed, as opposed to compressed. Figure 2 illustrates the movement, as well as the transformation, of data through the modem’s MCU, DPU, and DAA.

In the next section, we discuss various traditional dialup modem classification schemes.

CLASSIFICATION SCHEMES

Dialup modems can be classified on several salient dimensions. At a functional level, they can be distinguished from one another based on their architectural configuration. Modems also can be further classified based on *locality* (internal versus external), *transmission mode* (simplex versus half-duplex versus full duplex), and *synchronicity* (asynchronous versus synchronous). Each classification scheme is discussed next.

Architecture

An architectural classification is based on whether the MCU, DPU, and DAA functionalities are part of the physical modem or part of the computer. For example, if the MCU, DPU, and DAA functions are performed solely by the modem, then it is referred to as a *controller modem*. Conversely, if the MCU, DPU, and DAA functions reside on the PC, the modem is referred to as a *software modem*. Finally, if the MCU is on the PC but the DPU and DAA reside on the modem, then it is referred to as a *controller-less modem*.

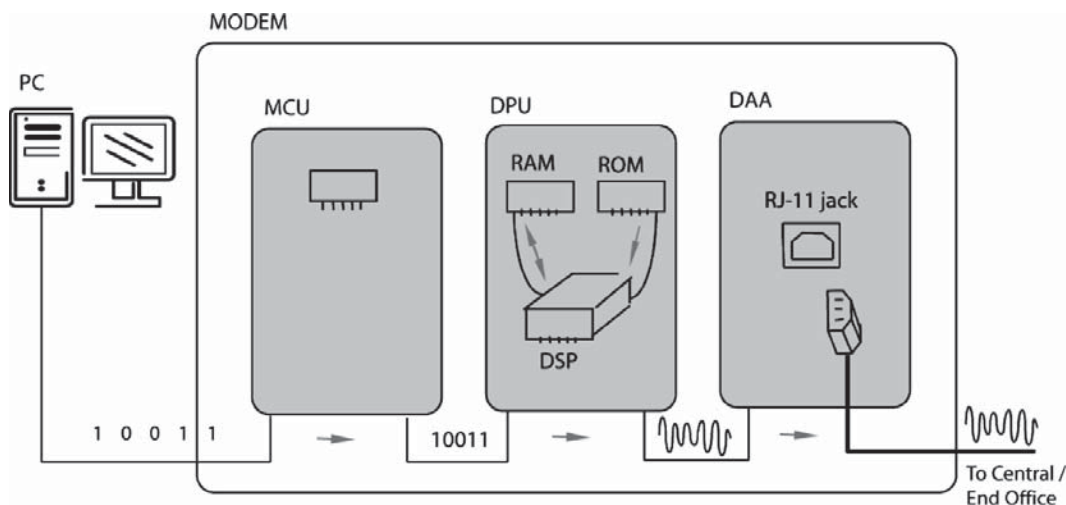

Figure 2: Modem functionality

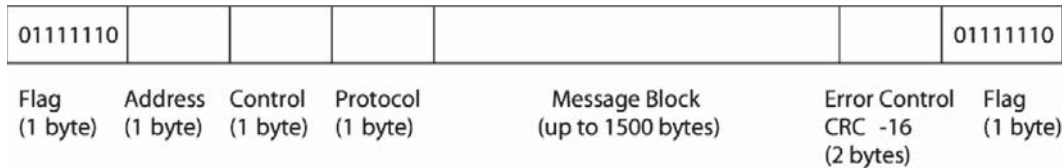

Figure 3: Point-to-point packet

Locality

Modems can be broadly classified as either *internal* or *external*. The former refers to a modem attached to a PC’s expansion slot, whereas the latter refers to a stand-alone modem that lies between a PC and the POTS connection—for example, one that connects via external serial, parallel, USB, or PCMCIA jacks or slots. It is important to note that most current PCs ship with internal modems, although expansion slot-based broadband connectivity cards are still frequently used (e.g., 802.11 g PC-MCIA and USB wireless cards).

Transmission Mode

Modems can also be classified based on their mode of transmission: as *simplex*, *half-duplex*, or *full duplex*. The distinction is based on how data may flow between two or more networked devices. In other words, simplex is data flow in one direction only; half-duplex is data flow in both directions, but not at the same time; and full duplex is data flow in both directions at the same time.

Synchronicity

Lastly, *synchronicity* refers to the way in which modems transmit characters or data. Asynchronous modems rely on start-and-stop bits to demarcate characters or packets

and frames, whereas synchronous modems use clocking to separate characters or packets and frames, the latter being much faster. An example of a synchronous *point-to-point protocol* (PPP) packet, typically used for Internet access over dialup modems (Wikipedia 2006 “Internet”), is presented in Figure 3.

In the next section, modem standards are discussed.

MODEM STANDARDS

Standards are paramount for achieving interoperability. Essentially, standards ensure that hardware and software from different vendors can work together—that is, they define a set of rules known as *protocols* (Dennis 2002). Two of the more well-known standards are the *open systems interconnectivity* (OSI) and Internet (TCP/IP) protocol stacks. Although the former was developed by the International Organization for Standards (ISO) in 1984 and the latter emerged from the Internet paradigm (Wikipedia 2006 “OSI”), they remain important conceptual foundations (especially the latter) on which most commercial data networks are built and managed today. As an example, the Internet protocol stack defines five interdependent layers, each of which performs a specific set of operations in the transmission of data between computing devices (Fitzgerald and Dennis 2005; Wikipedia 2006 “Internet”). See Table 1 for an overview.

Table 1: Protocol Stacks

OSI Model	Internet Model	General Tasks	Common Standards
7. Application layer	5. Application layer	Provide utilities for end user applications	HTTP; HTML IMAP, POP, SMTP MPEG; H.323 Middleware-RPC; MOM; CORBA/IOP; CICS; DTP
6. Presentation layer		Formats data for the presentation to end user	
5. Session layer		Initiating, maintaining, and terminating user sessions	
4. Transport layer	4. Transport layer	Breaks up messages into manageable blocks	TCP; SPX
3. Network layer	3. Network layer	Addresses and determines the route of messages	IP; IPX
2. Data link layer	2. Data link layer	Creates start and end blocks; determines when to transmit; error checking	Ethernet; ATM; FDDI ISDN; PPP
1. Physical layer	1. Physical layer	Physically connects the user to the network	Cat 5; Cat 3; twisted pair; coax; fiber; wireless

Table 2: ITU-T Modem Standards

Standard	Properties
Bell 103	300 bps, frequency modulation (FSK)
V.22	1200 bps, phase modulation (PSK)
V.22bis	2400 bps, quadrature amplitude modulation (QAM)
V.32	9600 bps; 4800 bps and 9600 bps fallback; quadrature amplitude modulation (QAM)
V.32bis	14400 bps; 12000 bps and 7200 bps fallback; trellis-coded modulation (TCM)
V.34	28800 bps; 24000 bps and 19200 fallback; trellis-coded modulation (TCM)
V.34+	Increased data rate of V.34 to 33600 bps
V.42	Error correction
V.42bis	Lempel-Ziv data compression
V.44	Improved V.42bis data compression; compression used in V.92 standard
V.90	33600 bps upstream; 56000 bps downstream; single analog digital conversion
V.92	48000 bps upstream; 56000 bps downstream; single analog digital conversion modem on hold; quick connect increases upstream

Although the ISO is credited with standardizing the networking layers, it is the work of other standards-making or enforcing bodies such as the Institute of Electrical and Electronics Engineers (IEEE), International Telecommunications Union–Telecommunications Group (ITU-T), the American National Standards Institute (ANSI), and the Internet Engineering Task Force (IETF) that ensures interoperability at and between each layer. Two of these organizations—IEEE and ITU-T—are salient to the current context. The IEEE is the standards-making body for wireless modems (we will discuss these devices later), whereas ITU-T, a technical standards body of the United Nations, governs the standards for dialup modems. A summary of the most salient ITU-T modem standards (all starting with a “V”) is presented in Table 2.

In reviewing the ITU-T and IEEE modem standards, the three key concepts on which modem standards rest emerge: modulation, error checking, and compression. Before visiting each concept in greater detail, we first broach the topic of baud rate and data rate.

Data Rate

Data rate can be defined as the number of symbols or symbol spaces transmitted per second multiplied by the number of bits per symbol or symbol space. *Baud rate* can be defined as the number of times per second that the transmission signal can or does change. As such, the term *symbol rate* is synonymous with baud rate. For example, if the circuit’s baud rate is 1200, then 1200 symbols can be transmitted in one second. In other words, if one bit of data was transmitted for each symbol or symbol space, then the data rate would also be 1200 bps. However, if two bits were sent per symbol and the baud rate was 1200 bps, then the effective data rate would be 2400 bps (2 bits per symbol = 1200 symbols per second = 2400 bps). Note that

baud and data rate are different concepts: The first is a change in symbols per unit of time, whereas the latter is the number of bits of data sent per unit of time. However, they are equivalent whenever a single bit is transmitted per symbol or symbol space.

In addition to baud or symbol rate and bits per symbol, several factors influence effective data rates. First, noise may be a problem in the analog local loop, or last mile, depending on the type and quality of the transmission medium. For instance, twisted-pair copper wire tends to be antenna-like, absorbing electromagnetic and radio frequency signals that effectively corrupt the original signal and reduce data rates. Second, the type of modulation scheme invoked impacts the number of bits transmitted per symbol or data rate. Third, error checking, although necessary, reduces the effective data rate because of the additional data that are appended to each message for the purposes of detecting and correcting errors. Lastly, data compression algorithms, unlike the other three factors, may be used to increase the effective data rate by reducing the total number of bits that need to be transmitted (in some instances, a ratio of 1:6).

The first factor—noise—is external to the modem itself—that is, it is an issue with the circuit or connection media (e.g., twisted-pair, fiber) and, in the context of this discussion, needs no further elaboration. The last three factors—modulation, error checking, and data compression—are fundamental to modem standards. As such, they are elaborated on in greater detail next.

Modulation

Modulation refers to the way in which the shape of a carrier wave can be meaningfully modified so as to increase the number of bits per symbol or data rate. Carrier waves, or voice-grade analog waves, have three important

Figure 4: Amplitude modulation

Figure 6: Phase modulation

properties: amplitude, frequency, and phase. *Amplitude* refers to the height of the wave (the human ear recognizes this property as loudness), *frequency* refers to the length of the wave (the human ear recognizes this property as pitch), and *phase* refers to the wave's initial direction. Based on these wave characteristics, three basic modulation techniques emerge: amplitude, frequency, and phase modulation.

In *amplitude modulation* (also called *amplitude shift keying*), the height of the wave is systematically varied. One height can be used to represent a 0, and the other height can be used to represent a 1 (see Figure 4).

In *frequency modulation* (also called *frequency shift keying*), the number of waves per symbol space is systematically varied. One frequency can be used to represent a 0, and another can be used to represent a 1. For example, 2400 Hz can be used to represent a 0 during one given symbol space (if the baud rate is 300, then the symbol space would be 1/300 of a second), and 1200 Hz can be used in another symbol space to represent a 1 (see Figure 5).

In *phase modulation*, the direction (e.g., up to the right or down to the right) that the wave starts out at the beginning of a symbol space is systematically varied. One phase can be used to represent a 0, and another can be used to represent a 1. For example, in one symbol

Figure 5: Frequency modulation

space, the carrier wave can be forced up and to the right, representing a 1; and, in another symbol space, the carrier wave can be forced down and to the right, representing a 0 (see Figure 6).

Based on the properties of binary data (1 or 0 only), increasing the bits per symbol beyond 1 would require creating a number of amplitudes or modulations equal to the maximum number of possible combinations for a given number of bits. For example, if one wanted to transmit two bits per symbol, then four different wave heights, frequencies, or phase shifts would be needed (e.g., 11, 10, 01, and 00). Similarly, if three bits per symbol were desired, then eight different modulation levels would have to be defined (e.g., 111, 110, 101, 100, 011, 010, 001, and 000). In general, if n is defined as the number of bits per symbol or symbol space, then the formula for determining the appropriate number of modulations, regardless of modulation technique, is 2^n (2 raised to the number of bits per symbol).

Many of the more sophisticated modulation standards combine modulation techniques to maximize the number of bits per symbol (e.g., QAM and TCM). For example, in *quadrature amplitude modulation* (QAM), eight different phases and two different amplitudes are combined. The net result is a modulation technique that can transmit four bits per symbol—that is, it affords the creation of sixteen unique symbols, each defining one of sixteen different four-bit combinations ($2^4 = 16$). Building on QAM, *trellis-coded modulation* (TCM) can transmit 6, 7, 8 and 9.8 bits per symbol (Fitzgerald and Dennis 2005).

Error Checking

Error checking refers to the way in which modems append outgoing data and evaluate incoming data for errors. Like other modem protocols, error checking also has experienced considerable evolution (see Table 3). In general, if a data block is found to be error free, then the receiver transmits an *acknowledgment* block (ack). If it is not error free, then the receiver transmits a *negative acknowledgment* block (nack). The nack then notifies the sender that a specific data block, or frame, had errors and needs to be resent.

Table 3: Error-Detection Protocols

Error Protocol	Block Size	Checking Algorithm
X Modem	128 bytes	Checksum
Y Modem	1024 bytes	Cyclical Redundancy Check
Z Modem	512 bytes	Cyclical Redundancy Check
Kermit	Dynamic	Checksum
V.42 (LAPM)	128 bytes	Cyclical Redundancy Check

Data Compression

Data compression refers to the process of finding commonality in data and transmitting a shortened version of the message for the purpose of increasing data throughput. Current compression protocols (V.44) like Lempel-Ziv (LZ) compress data at ratios as high as 6:1 (Fitzgerald and Dennis 2005). Essentially, LZ compression creates a dictionary of two-, three-, and four-character combinations in any previously uncompressed set of data and represents repeat occurrences as dictionary indexes, as opposed to the actual character combination. For example, a V.34+ modem utilizing LZ compression (V.42bis) can, depending on the file type (e.g., text, graphics, executable), produce effective data rates in excess of 200 Kbps (Fitzgerald and Dennis 2005). Moreover, V.92 modems (utilizing V.44 compression), depending on the file type, are purported to improve throughput by as much as 120 percent relative to V.42bis. Note, however, that the relative effects of V.42bis and V.44 compression standards on actual throughput vary widely in the extant networking literature. Table 4 illustrates the compression effects of V.24bis and V.44 on text and graphics files (Digit-Life 2004).

Thus far, the primary focus of the chapter has been on dialup modems. In the next section, several broadband technologies—cable, DSL, and wireless modems—are reviewed. Note, however, that many of the concepts discussed to this point (e.g., standardization, modulation, compression, and error checking) are foundational for broadband modems as well. In other words, binary or

digital data must still be modulated and demodulated, compressed and decompressed, and checked for errors.

BROADBAND MODEMS

Despite advancements in modem technology (e.g., V.92), the unrelenting integration of voice, video, and data on the Internet and World Wide Web continues to outpace traditional voice-grade circuits in ways that greatly diminish quality of service. Furthermore, traditional dialup modems may even be prohibitive for many of today's data-intensive applications and services (e.g., videoconferencing and online video games). A new generation of modems called *broadband modems* has thus been developed to overcome the limitations associated with traditional dialup modems. In this section, several broadband modems are reviewed: cable, DSL, and wireless.

Cable Modems

Several industries offer broadband alternatives to traditional dialup modems. One such industry is cable television. Many of today's cable entertainment providers, in addition to cable television, provide shared multipoint access to the Internet. Cable modems, in theory, can provide download speeds as high as 55 Mbps and upstream speeds of 10 Mbps. Today, however, speeds for both downstream and upstream are typically no greater than 2 Mbps (Fitzgerald and Dennis 2005). Currently, cable infrastructures (i.e., private *hybrid fiber-coax*, or HFC, networks) remain proprietary and therefore lack standardization. Although several protocols are in use, the de facto protocol is *data over cable service interface specification* (DOCSIS). Figure 7 shows a typical cable modem configuration.

In general, cable modems work by transmitting data to a line splitter within or near the customer's premise. The line splitter combines (upstream) or splits (downstream) the television and Internet data streams. From the splitter, the signals are carried to the cable company's fiber node. The fiber node contains an *electrical-to-optical* converter that converts cable signals to fiber-optic signals. The fiber node then connects directly to the cable company's distribution hub via a separate downstream and upstream fiber-optic cable. The upstream data is then processed by the cable company's *cable modem termination service* (CMTS), which handles various Internet protocols necessary for routing data traffic.

Table 4: Relative Compression Efficiency of V.42bis and V.44

Compression	Text File		Graphics File	
	Units	Effective Data	Units	Effective Data
None	1.00	1017	1.00	1018
V.42bis	5.53	5617	2.39	2427
V.44	7.16	7282	3.29	3344

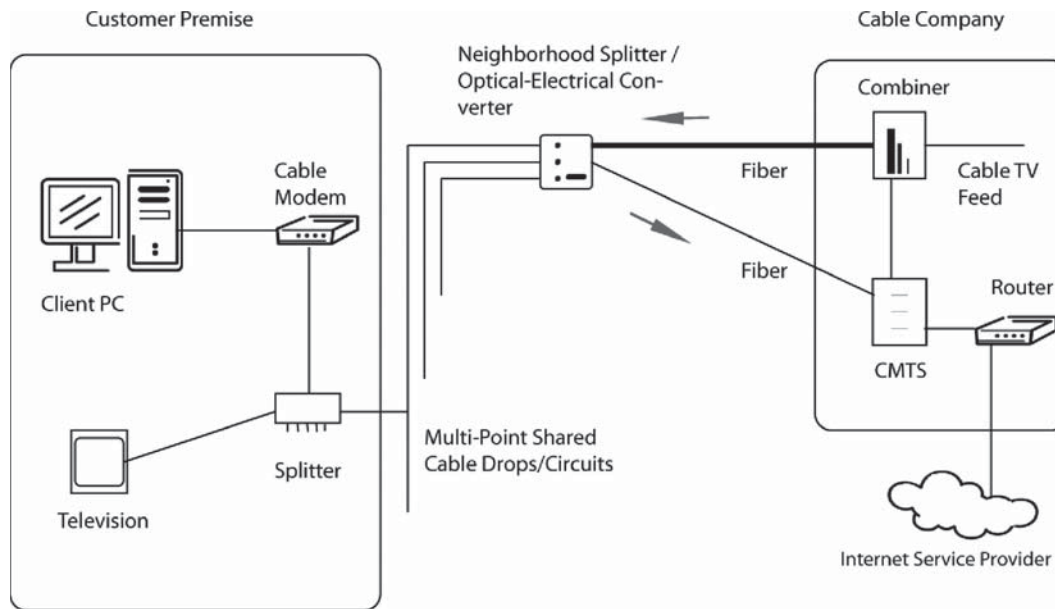

Figure 7: Cable modem example configuration

Downstream traffic, which may include both Internet data and television video, is merged via the cable company's combiner. The combiner then transmits the data by way of fiber optic to the cable company's fiber node. The optical-to-electrical converter on the fiber node then converts the fiber signal to a cable signal and sends it down the cable drop. The line splitter on the customer's premise then separates the data streams into Internet and television data and sends the Internet data to the modem, which either converts it for computer use or retransmits it. It is important to note that all cable users on a given cable drop share the multipoint cable circuit, and, as such, the cable modem at each premise may actually process much of the other users' downstream and upstream data, making security an issue.

Digital Subscriber Lines

Digital subscriber lines (DSL) are another broadband alternative. Unlike cable modem technology, DSL technology is a point-to-point technology. As such, compared to cable modems, privacy becomes less of a concern, and the overall bandwidth is dedicated, as opposed to being shared by 300 to 1000 cable users. Because DSL is a telecommunications technology, the ITU-T acts as the standards body. Digital subscriber lines overcome traditional voice-grade circuit limitations in the last mile or local loop by circumventing the traditional voice-grade switching equipment at the central or end office. Dialup limitations do not so much lie in the twisted-pair copper but more so on the voice-grade switching equipment, which is limited to 4000 Hz. The copper wires in the local loop have a physical capacity of as much as 1 MHz (1 million cycles per second). Telephone companies leverage the available bandwidth by simply placing different terminating

equipment at the customer's premise and at the central office. Figure 8 illustrates a common DSL configuration.

Similar to cable modems, the *customer's premise equipment* (CPE) may include a splitter to separate traditional voice-grade data from other data. The DSL modem, sometimes referred to as a *DSL router*, combines the functions of a modem and the functions of a *frequency division multiplexer* (FDM). Essentially, FDM creates several logical circuits from one physical circuit. This is done by transmitting voice-grade data at 4 kHz and, in many instances, creating two additional and distinct frequencies for upstream and downstream data, the latter being considerably larger in bandwidth.

Digital subscriber line modems transmit data to a telecommunication company's central office, specifically the telephone company's *main distribution facility* (MDF). Similar to the CPE splitter, the MDF has a splitter that directs voice-grade data to the telephone network and all other data to the phone company's *digital subscriber line access multiplexer* (DSLAM). Next, the DSLAM converts the data and either transmits it as *asynchronous transfer mode* (ATM) data for further retransmission (e.g., to an ISP) or directly routes it through the phone company's point-of-presence (its own ISP). The reverse process (downstream) is relatively the same.

Many types of DSL are currently available throughout the world. The most common is *asymmetric DSL* (ADSL). Asymmetric DSL uses FDM to create three logical circuits: one 4-kHz voice-grade circuit, one 384-Kbps circuit for upstream, and one 1.5-Mbps high-speed circuit for downstream. A second common type of DSL is *very-high-data-rate DSL* (VDSL). VDSL, or *short-loop ADSL*, is used for distances of less than 4500 feet. It also uses FDM to create three logical circuits from a single physical circuit, with theoretical data rates of 51.84 Mbps downstream and

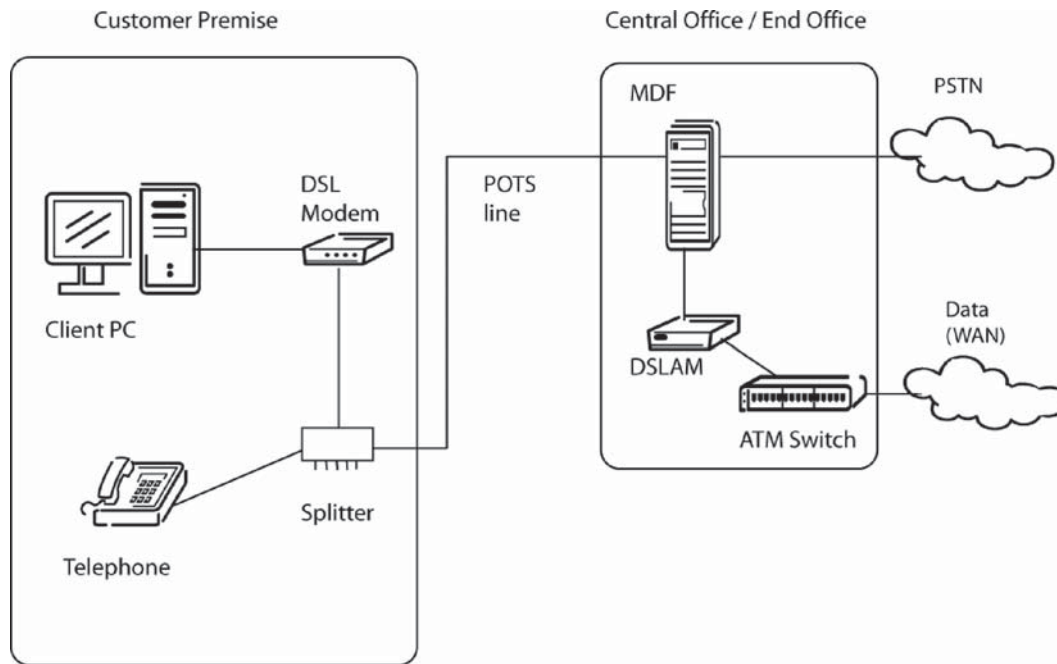

Figure 8: DSL example configuration

2.3 Mbps upstream on drops less than 1000 feet. A third type of DSL in use is *wireless DSL* (WDSL). This remains a good solution for instances in which transmitters have unobstructed line of sight. Both point-to-point and multipoint WDSL architectures are available. Both versions typically can provide data rates as high as 11 Mbps.

Wireless Modems

Wireless modems convert digital data into radio or cellular signals. These are transmitted to the nearest receiver (wireless access point or cell tower) and routed appropriately. Several standards are in existence and vary depending on the mobile device, transmitter, or application layer in use. For WLAN (WiFi and Bluetooth) and WiMAX standards, IEEE is the standards body (see IEEE 2006a, 2006b). Several standards for smaller handheld, mobile devices also exist, including *wireless application protocol* (WAP) and *wireless application environment* (WAE).

In general, cellular phone connections are markedly slower than V.92, cable, and DSL. They do, however, provide ubiquitous connectivity. Data rates, as well as signal footprints, vary considerably for WLAN and WiMAX technologies. Two 2.4-GHz WLAN standards remain popular today: 802.11b and 802.11g. The 802.11b standard provides data rates as high as 11 Mbps, and 802.11g provides data rates as high as 54 Mbps. For both, however, these are theoretical data rates, and data rates diminish quickly the farther one is from the wireless access point. In theory, WiMAX (IEEE 802.16) has the capability to deliver wireless services as far as thirty miles away. A single WiMAX tower is purported to have the capacity to deliver the

equivalent bandwidth of sixty T1 lines (1.544 Mbps each) and one hundred DSL or cable lines. Although the data rate and coverage (or footprint) for WiMAX are still in question, it is reasonable to expect even more impressive bandwidth and coverage as WiMAX and other emergent wireless technologies advance.

CONCLUSION

In this chapter, modems were defined and a brief history of dialup technologies was provided. The process of transmitting binary data via dialup modems was also presented. The salient functional components of a dialup modem—MCU, DPU, and DAA—as well as salient modem classifications, were also discussed. The important role of standards, as well as the primary bodies for standards making and enforcing for networking in general and modem-based technologies specifically were presented as well. Three primary concepts underlying modem standards—modulation, error checking, and data compression—as well as their impact on data rates were also discussed. Lastly, three broadband modem categories—cable, DSL, and wireless—were identified and presented as alternatives to the waning dialup standards.

With the introduction and proliferation of broadband technologies, as well as the relentless integration of voice, video, and data, the probability of seeing traditional or analog-digital hybrid modem data rates or adoption rates increase in any meaningful way is extremely suspect. Essentially, the dialup modem is to networking as the horse and buggy is to global transportation: It remains viable but is limited at best. The overwhelming trend in network

access and connectivity—at least in the local loop or last mile—has shifted and continues to shift toward both broadband wired (e.g., DSL, cable, Ethernet to the home, fiber to the home, and broadband over power lines) and wireless (e.g., 3G cellular data services and WiMAX) technologies.

GLOSSARY

American National Standards Institute (ANSI): The principal standards-setting body in the United States. ANSI is a nonprofit, nongovernmental organization that supports in excess of 1000 trade organizations, professional societies, and companies. ANSI is also a member of ITU-T and ISO.

Amplitude modulation: The form of modulation in which the amplitude of the carrier is varied in accordance with the instantaneous value of the modulating signal.

Asymmetric digital subscriber line (ADSL): A data-link layer technology that provides high-speed communication over traditional telephone lines.

Asynchronous transfer mode (ATM): A communication switch that affords transmission rates as high as 622 Mbps. ATM is especially well suited for multimedia transmission, including the integration of voice, video, and data.

Broadband: A type of data transmission in which a single medium can carry several channels at once.

Cable modem: A modem designed to operate over coaxial cable lines used by cable TV.

Controller-less modem: A modem in which the microcontroller is actually part of the computer device instead of the modem.

Controller modem: A modem that contains a microcontroller unit, a data pump unit, and a data access arrangement.

Data access arrangement (DAA): Provides the analog circuits that electrically isolate the modem from the phone line, separating the modem from the telephone line's higher voltage and allowing the modem to interface with the telephone network.

Data compression: A technique that allows devices to transmit or store the same amount of data in fewer bits.

Data pump unit (DPU): That part of the modem responsible for converting binary data to analog data.

Digital subscriber line (DSL): A data-link layer technology that provides high-speed communication over traditional telephone lines.

Digital subscriber line access multiplexer (DSLAM): The multiplexer used by telephone companies for connecting to, and handling, data transmitted on multiplexed DSL circuitry.

Echo cancellation: Used in higher-speed modems to isolate and filter out echoes when half-duplex transmissions use stop-and-wait automatic repeat request protocols.

Frequency division multiplexing (FDM): The technique of dividing a voice-grade circuit into subcircuits, each covering a different frequency range so that each circuit can be employed as though it were an individual circuit.

Frequency modulation: A form of modulation in which the frequency of the carrier is varied in accordance with the instantaneous value of the modulating signal.

Institute of Electrical and Electronics Engineers (IEEE): An organization composed of scientists and students and best known for developing standards for the computer and electronics industry.

Internet Engineering Task Force (IETF): A large, open international community of network designers, operators, vendors, and researchers concerned with the evolution of the Internet architecture and its smooth operation.

International Organization for Standards (ISO): An international standards-making body best known in data communications for developing the internationally recognized seven-layer network model called the open systems interconnection (OSI) reference model.

International Telecommunications Union (ITU): An intergovernmental organization through which public and private organizations develop telecommunications. The ITU was founded in 1865 and became a United Nations agency in 1947. It is responsible for adopting international treaties, regulations, and standards that govern telecommunications.

Microcontroller unit (MCU): A modem's internal processor or controlling unit.

Phase modulation: A form of modulation in which the phase of the carrier is varied in accordance with the instantaneous value of the modulating signal.

Quadrature amplitude modulation (QAM): A sophisticated modulation technique that combines eight phases and two amplitudes to generate a unique four-bit code for each one of sixteen unique modulations or symbols.

Very high data rate digital subscriber line (VDSL): A DSL technology designed to provide very high data rates over very short distances of less than 4500 feet.

Wireless fidelity (WiFi): Generically used when referring to any 802.11 network.

Wireless local area network (WLAN): A type of local-area network that uses high-frequency radio waves rather than wires to communicate between nodes.

WiMAX: The name commonly given to the IEEE 802.16 standard.

Wireless modem: A modem that accesses a private wireless data network or a wireless telephone system.

INTRODUCTION

The Internet consists of millions of digital passages that carry signals all over the world. These conduits that connect us to the World Wide Web come in many shapes, sizes, and modes. The bewildering assortment and seemingly endless conduits—more commonly referred to as *communication media*—that are used to connect computers together can be boiled down to two types: conductive cable and wireless. Conductive media is simply a hardwired connection that requires someone to physically join network devices with some type of cable. The three major types of cable are coaxial, twisted-pair, and fiber-optic. The focus of this chapter is on conducted communications media. Wireless communication is the alternative to conducted communications media and is accomplished using a variety of broadcast transmission technologies, including radio, terrestrial microwave, and satellite communications.

To aid in understanding conductive communications media, a short explanation of network transmission basics is discussed, followed by a detailed exploration of the three major types of media mentioned earlier. In addition, we present the similarities and contrasts between these media. Finally, the suitability and application of each type of conducted media along with security concerns is discussed.

OVERVIEW OF NETWORK TRANSMISSION BASICS

Network Transmission Basics

When computers communicate over the Internet or on private networks, they must follow certain communication protocols. In short, each computer that connects to a network must follow rules that govern the type of hardware and software that is used for access to the network. These protocols consist of signal types and speeds, cable layouts, and communications access schemes.

Baseband and Broadband

Bandwidth is the range of frequencies that a particular network transmission media can carry. It also reveals the maximum amount of data that can be carried on the medium. A baseband transmission is a single fixed signal that uses the entire available bandwidth. Baseband signals use a single channel to communicate with devices on a network; this allows computers to transmit and receive data on one cable (Tittel and Johnson 2001). Baseband communications are typically used for *local area networks* (LANs). When LANs expand into a *metropolitan area network* (MAN) or a *wide area network* (WAN), baseband systems do not provide the bandwidths that are adequate for these larger networks.

Network connections that attach several LANs together, such as MANs or WANs, or that allow remote access from external users or networks to local servers often require multichannel bandwidths because of increased traffic flow. Broadband transmissions help to meet these needs. In contrast to the discrete digital signals produced in baseband communications, broadband transmission generates an analog carrier frequency that carries multiple digital signals or multiple channels. This concept is much like cable television systems that carry many channels on one cable.

The decision to use baseband or broadband is determined by the application. If the network consists of a single LAN, then baseband would be the best choice. If an organization has computer networks that spread over several geographic areas, then multiple channels of communications between locations may be needed; this can be achieved only through broadband applications. Note that it is the network type and the particular network device that determines whether a signal is baseband or broadband, not the transmission media.

Cable Access Methods

A *cable access method* is how data is placed on the transmission media. Data are formatted into small pieces called

packets. A packet contains header and trailer information about the contents, source, destination, error checking, and the actual data. A packet typically contains a specific amount of information, normally 1 to 2 kilobytes, that is defined by the particular network protocol being used. It is a lot like an envelope used to hold a letter to be mailed. The outside of the envelope contains a destination address along with sender information. This information is used by the postal service to deliver the mail to its destination. When a wrong destination address is used, the postal service can notify the sender by means of the return address. Network packets are handled in a similar way (Tittel and Johnson 2001).

Packets are placed on the communications line in several ways. Typically, the communication media used in a LAN will be shared by all network devices. In most cases, only one device can transmit information on the communication media at a time. This will often be in the form of a broadcast. A broadcast by a computer will be received by all of the devices connected to the particular network segment. For example, Ethernet, a widely used LAN protocol, uses a cable access method called *carrier sense multiple access with collision detection* (CSMA/CD). This method is a lot like a two-way radio broadcast, which allows only one person to talk at one time. CSMA/CD requires each participating network workstation to first listen to the communication line to determine whether it is clear before attempting to broadcast a packet of information, because it is possible that two or more workstations will begin broadcasting their packets at almost the same time. If this occurs, then the *collision detection* (CD) feature of CSMA/CD will instruct the conflicting workstations to cease transmissions and assign a random delay before they are allowed to attempt to send another packet of data. Without a random delay, the colliding workstations would continue to rebroadcast at the same time, causing more collisions. It should be noted that a small number of collisions are normal but should not exceed 5 percent of all network traffic. Occasionally, a defective *network interface card* (NIC) may cause excessive collisions by constantly broadcasting packets. This is called a *broadcast storm* (Tittel and Johnson 2001).

A similar access method used by AppleTalk networks is called *carrier sense multiple access with collision avoidance* (CSMA/CA). This scheme is similar to CSMA/CD except that it attempts to avoid collisions altogether. Network devices accomplish this by sending a short broadcast requesting control of the network segment before sending a packet. This helps prevent collisions of complete packets, thus reducing network traffic because of rebroadcasting packets (Tittel and Johnson 2001).

Another type of access method is called *token passing*, and it is used by token-ring protocol. Token passing eliminates network collisions altogether by passing a token from node to node on the network in one direction. A *token* is similar to a packet. When a network device receives a

token, it examines it to determine whether its contents are for that particular node. If not, then the network node rebroadcasts the token to the next device on the network. When the token finds its destination, it unloads the data and rebroadcasts an empty token to the next device. The empty token will ask each passing node whether it has any data to send. The empty token is passed on down the line until a device generates information to place in the empty token (Tittel and Johnson 2001).

Network Topologies

A *network topology* is the physical cable layout or configuration. There are three basic types: star, bus, and ring. Each network protocol (i.e., Ethernet, token ring) will specify the cable type and topology supported. The *star* topology, as illustrated in Figure 1, requires a central wiring point for all network devices on a particular network segment. A device called a *hub* or *concentrator* is used to serve this purpose. A hub is a multiport repeater that regenerates signals received. In some applications, a device called a *switch* is used. A switch is more intelligent than a hub because it can learn which devices are connected to its ports and send packets directly to the destination port only, thus reducing network traffic.

The *bus* topology (see Figure 2) requires no special external device for computers to connect with it. It consists of network nodes connected to the communications media via a special T-connector that connects the computer's NIC to the bus (see Figure 3). Notice in Figure 2 that a small box is shown at both ends of the bus. This represents a terminator that is required for this cable layout (see Figure 4). Its purpose is to prevent *signal bounce*, which occurs when a cable is not terminated. Signal bounce is the result of a broadcast signal that continues to oscillate. The terminator is used to absorb the signal once it has reached the end of the cable, thus eliminating signal bounce.

The *ring* topology (see Figure 5) is similar to bus topology in that each computer is connected directly to its neighbor without the need for a hub or other special device. The big difference between the two is that ring

Figure 1: Star topology

Figure 2: Bus topology

Figure 3: T-connector

Figure 4: Terminator

Figure 5: Ring topology

topology provides a closed-loop design that does not require termination.

In some applications, more than one topology may be used. This is typically called a *mesh* or *hybrid* topology. This is often the case when different types of communications media are used for the same network. Later in this chapter, we discuss the characteristics of different network cables and see that each cable type is best suited for a particular topology. In some situations, a network might need to utilize different cable types in order to accomplish the best overall network performance, which might require the use of multiple topologies.

A mesh or hybrid topology does not necessarily require the use of different communications media. For example, the token ring protocol uses a topology called a *star-wired ring* that may utilize only one type of cable, as shown in Figure 6. In this example, *multistation access units* (MAUs) or concentrators are used to connect the network devices. The MAUs are then connected to each other in a physical ring configuration. The physical connection to the MAU represents the star portion of the topology; however, a logical continuous ring is actually created when using MAUs and the token-ring cabling system. Figure 6 only shows the physical connections even though a token is passed into and back out of each MAU

Figure 6: Star-wired ring

port that has a device connected to it in a continuous loop that forms the logical ring.

Each topology has its advantages and disadvantages. For example, the bus topology has the advantage of low cost because it does not require any special devices to connect computers. A disadvantage, however, is that if there is a break in any of the cables, the entire network segment will go down because of a loss of termination. The task of finding the broken cable could be somewhat difficult without the help of a fairly expensive cable analyzer. On the other hand, computers connected to a star topology would most likely remain operating on the network if one of the cables malfunctioned between a device and a hub. Star topology requires more wire than a bus topology, and it also requires hubs or switches, which adds more cost. Ring topology has an advantage over bus and star topologies because it typically provides an alternate path for data transmission in case of a cable break. For instance, a star-wired ring topology provides a logical continuous ring that provides a redundant path if a cable were to be cut.

The purpose of this section on network transmission basics is to establish the concepts and characteristics related to conducted transmission cable. Each media type differs in physical and electrical-optical characteristics as well as in application. The following section discusses the three major types of conducted transmission cable: coaxial, twisted-pair, and fiber-optic.

COAXIAL CABLE

Coaxial (or simply *coax*) *cable* is used in a wide range of applications, including television, radio, and computer network communications. This section looks at the physical makeup of coaxial cable and the specific characteristics that distinguish different types.

Components

Coaxial cable consists of an inner and outer conductor that share the same axis, which is how it got its name, coaxial (Carr 1999). The inner conductor, sometimes called the *conducting core*, is typically made of a copper alloy. Most applications use a solid core, except where flexibility is required, and then a stranded core may be used. The outer conductor is either braided metal or foil; this acts as a conductor and a shield to reduce interference. An *insulator*, or, more accurately, a *dielectric*, is between the two conductors. Depending on the type of coax, this material is made out of Teflon or an inert gas. Finally, for protection, there is an *outer sheath* that surrounds the inner components. This is made from polyvinyl chloride (PVC) or special fire-retardant material for installations where wire must be run in the plenum areas above the false ceilings in a building (Carr 1999; Tittel and Johnson 2001).

Coaxial cables come in a variety of forms: flexible, helical line, and hard line. Flexible coax is made of flexible material in the outer conductor, typically braid or foil. This cable is mostly found in LANs and home television-to-antenna connections. Helical line coax is a semiflexible cable that consists of a slightly more rigid, spiral-wound outer conductor. Normally, this type of cable is used for

network backbones or interconnections between networks that require long cable runs. This type of cable is able to carry a signal over longer distances at higher frequencies than can flexible cable types. Hard-line coaxial cable is used to connect equipment that transmits in the microwave frequency range. This form of coax uses a thin-walled pipe as an outer conductor that is rigid and difficult to work with. As the frequency of a transmitted signal increases, there is a greater chance of the signal radiating beyond the outer conductor, which also acts as a shield, thus resulting in signal loss. In the case of external electromagnetic interference, the type of outer conductor will determine which frequencies will be rejected from the transmitted signal (Carr 1999).

Another characteristic of coaxial cable is its *impedance*. Impedance, measured in ohms, is the resistance of a cable to the transmitted signal (Tittel and Johnson 2001). Carr (1999) stated that the lowest loss of signal occurs at higher impedances; however, more power can be achieved when the impedance is low. Cable television uses coaxial cable rated at 75-ohm impedance because of its lower signal attenuation with long cable runs. Most network and radio applications use 50-ohm impedance as a middle ground between low signal loss and more power.

Cable manufacturers use a *radio government* (RG) specification for the coaxial cables they produce. Cable television uses RG-6, RG-11, or RG-59 spec cable. All of these are rated at 75 ohms. RG-6 and RG-11 are larger diameter cables used for major trunk lines. RG-59 is employed between the trunk lines and the customer's television.

RG-58 and RG-8 are 50-ohm cables used for computer network communications. As does cable television, computer networks use trunk lines to connect network segments together. RG-8 is the cable used for trunk lines or network backbones and is often referred to as *thickwire Ethernet*, or *thicknet* for short. RG-58 is used with *thinwire Ethernet*, or *thinnet*, to interconnect smaller segments of the network (Tittel and Johnson 2001).

Coaxial Cable Network Applications

Thickwire Ethernet

Thicknet (RG-8) is typically used as an Ethernet backbone to connect various network segments together. Thicknet can be used to directly interconnect devices on the network, but usually thinnet is used for this purpose. Thicknet uses the bus topology with the CSMA/CD cable access method. Normally it is used as a network backbone, which consists of a length of RG-8 cable with network devices, such as hubs, connected to it. Each device connected to the backbone requires a special device called a *transceiver*. The transceiver is connected to the coax by use of a *vampire tap* (see Figure 7). A special cable then attaches the transceiver to the device through its *attachment unit interface* (AUI) port (see Figure 8).

Each conducted transmission cable exhibits certain standardized characteristics that describe its advantages and disadvantages within network applications. Table 1 describes thickwire Ethernet characteristics. Each cable type reviewed contains similar specifications. The reason there is a maximum length is because of *attenuation*, which is the reduction in signal strength that occurs

Figure 7: Thickwire coax attached to transceiver via vampire tap

Figure 8: AUI cable connected to a transceiver

Table 1: Thickwire Ethernet Specifications

Characteristic	Specification
Maximum cable segment length	500m
Maximum total network length	2500m
AUI (drop cable length)	50m
Maximum number of devices per segment	100
Maximum number of segments	Five connected by four repeaters, with not more than three populated segments
Bandwidth	10Mbps*
Termination	50 ohms
Cable access method	CSMA/CD

* Megabits per second

as cable lengths increase. At some point, the signal loss becomes excessive and causes the network to stop functioning. As with this and other wire specifications, cable manufacturers rely on Institute of Electrical and

Electronics Engineers (IEEE) standards when producing their products. The Ethernet standards for thicknet and thinnet are covered in the IEEE 802.3 specification (Tittel and Johnson 2001).

Table 1 shows a total network cable length of 2500 meters (m), which is based on the *5-4-3 rule*. This rule states that each network cannot exceed a total of five cable segments connected by four repeaters, with not more than three of the segments populated by nodes (see Figure 9).

Figure 9 shows five complete cable segments. Each segment is connected to a device called a *repeater*. A repeater is used to compensate for the attenuation caused by cable lengths that exceed 500 m for thicknet. Its function is to amplify and repeat what it receives so that its signal will be strong enough to reach another repeater or the end of the next cable segment. Note that two segments do not have any network devices connected to them. This implies that only three of the five segments may have network devices attached. Tittel and Johnson (2001) stated that in reality this means that any two network devices cannot be separated by more than four repeaters (five segments) with three populated segments. So the 5-4-3 rule does not say a network is limited to only five segments. It states only that network devices cannot communicate with each other if they are separated by more than five segments. In addition, the 5-4-3 rule helps with signal timing and reduces the collision activity.

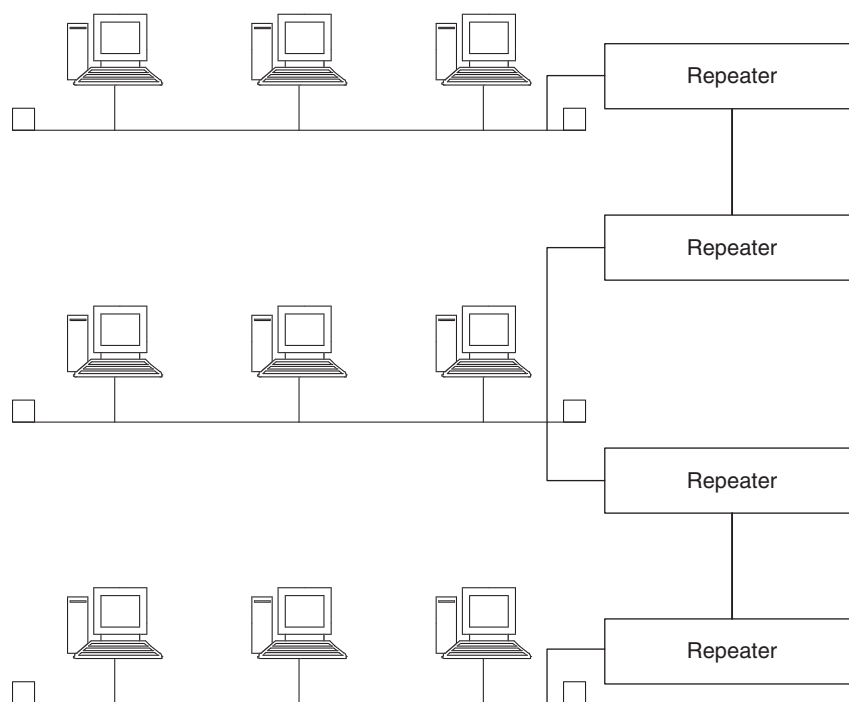

Figure 9: 5-4-3 rule diagram

The AUI or drop cable length refers to the cable that attaches to the transceiver unit connected via the vampire tap to the thickwire Ethernet backbone. This type of connection is used to connect such devices as repeaters or hubs to the Ethernet backbone. The AUI cable must be less than 50 m long.

Table 1 shows a maximum of one hundred devices per segment for thickwire Ethernet. Every time a device is attached to an Ethernet backbone, there will be some signal loss. Any device attached beyond the limit is not guaranteed to function properly. When designing a network, these limits should not be pushed. If a segment is fully populated, then there is no room for expanding a network without adding another segment, assuming that the network does not already have the maximum allowable five segments.

Some IEEE specifications, such as bandwidth, are preset and cannot be altered. If the network bandwidth will not support the needs of the network, then a different protocol or standard will need to be used. The bandwidth specification of 10Mbps for thickwire Ethernet describes how much data can be transmitted, which ultimately determines the speed of communications. As with all bus topologies using coax, a terminator is required at both ends of the bus to eliminate signal bounce. Because thicknet coaxial cable is designed for 50-ohm impedance, a 50-ohm *terminator* is required. A terminator is simply a connector that has been retrofitted with a 50-ohm resistor between the inner and outer conductors.

Thinwire Ethernet

Networks can be quickly set up using little more than RG-58 cable and a few connectors. Thinwire cable is commonly used to interconnect computers or other network devices on a network segment using the bus topology.

Figure 10: British naval connector or bayonet nut connector (BNC)

In the past, thinnet was one of the most popular transmission cables for Ethernet networks because of its low cost and ease of setup.

Thinnet cable uses a special connector called a *British naval connector* or *bayonet nut connector* (BNC) (see Figure 10). Computers and other network devices are connected to the bus topology by way of a BNC T-connector (see Figure 3), which connects to the NIC. The NIC is a transceiver that provides the physical connection between the network device and the transmission media. In addition, the NIC is responsible for packaging the data coming from the network device into a form acceptable to the network cable.

As with thicknet, thinnet follows the IEEE 802.3 standard with regard to the use of RG-58 coaxial cable. Table 2

Table 2: Thinwire Ethernet Specifications

Characteristic	Specification
Maximum cable segment length	185 m
Maximum total network length	925 m
Maximum number of devices per segment	30
Maximum number of segments	Five connected by four repeaters, with three populated segments
Bandwidth	10Mbps
Termination	50 ohms
Cable access method	CSMA/CD

summarizes these cable specifications. Notice that thinnet characteristics are similar to thicknet except in cable lengths and number of devices per segment. Also, there is no specification for a drop cable for thinwire Ethernet because the NIC serves the same function as the external transceiver used by thicknet (Tittel and Johnson 2001).

The physical characteristics of thinwire coax attenuate signals over shorter distances than does thickwire. This is typically not an issue because thinnet is normally used to interconnect computers within a relatively small area. In situations where computers need to be separated by more than 185 m, a repeater can be used to accommodate these devices. The low cost of this wire often outweighs the distance limitations.

The number of devices that can be attached to a thinnet bus topology is thirty. This is fewer than can be attached to thicknet because of the reasons noted in the previous paragraph for cable length. Be aware that a network can have more than one segment. With repeaters, thinwire Ethernet can support multiple populated segments. The 802.3 standard specifies a maximum of 1024 devices per network as long as the 5-4-3 rule is followed; however, with that many devices network performance would be dismal at best and thus not practical (Tittel and Johnson 2001).

In addition to network protocol standards for Ethernet and token ring, IEEE references cable-type standards such as 10Base5 and 10Base2 for thickwire and thinwire, respectively. The number 10 represents the bandwidth of the cable specification. *Base* refers to a baseband (single-channel) signal type, and the last number represents the maximum length of a network segment in meters rounded to the nearest hundred. For example, 10Base5 refers to a coaxial cable that carries a baseband signal transmitted at 10Mbps with a maximum segment length of 500m (thicknet). Thinnet is referenced by 10Base2, meaning a baseband signal with a 10-Mbps bandwidth at 200m, approximately. In reality, thinwire Ethernet can only support 185m segments. Twisted-pair and fiber-optic cables carry 10BaseT and 10BaseF IEEE cable standards. These are discussed in more detail later.

There are several advantages to using coaxial cables for computer networks. For LANs, RG-58 uses the bus topology, which offers lower cost options and ease of installation. Also, the outer shielding of coax provides moderate protection from interference. 10Base2 applications allow for fairly long cable runs compared with other cables such as twisted pair. The major drawback of coax is its narrow bandwidth compared with contemporary applications using twisted-pair and fiber-optic cable. Plus, thicknet installations can be somewhat difficult and expensive because of the rigidity of the cable, the rather difficult task of installing network connections, and the overall cost of the interface devices. Generally speaking, the days of coaxial cable infrastructures are waning. The majority of installations use twisted-pair and fiber optic cabling.

TWISTED-PAIR CABLE

Twisted-pair cable consists of one or more pairs of twisted wire. Twisted pair has a longer history than coaxial cable, but its usage was restricted to voice until the 1980s. Omninet or 10Net began to use twisted pair in the early 1980s for PC-based LANs. One of the first PC applications using twisted-pair cable was in 1984, when IBM introduced the token-ring network protocol. By the end of the 1980s, Ethernet technology began using twisted pair. Some advantages of twisted-pair over coaxial cable include its light weight and flexibility; in some cases, existing twisted-pair cables within buildings can be used without having to install new wiring (Network Magazine 1999).

Components

Twisted-pair media comes in two forms: *shielded twisted pair* (STP) and *unshielded twisted pair* (UTP). STP consists of several pairs of twisted wires that are surrounded by a foil shielding and an outer jacket or sheath. The number of wire pairs can vary from either two or four for basic telephone and network applications to hundreds of pairs for major communication trunk lines. Each wire within the pair consists of a solid or stranded copper center core surrounded by an insulating cover. Stranded wire is typically used where greater flexibility is required.

The twist in each pair of wire reduces *cross talk*. When a signal travels down the wire, it produces a magnetic field. If not controlled in some way, this can produce unwanted interference with other pairs of wire within the same cable (cross talk). The twist in the pairs works to reduce the effects of cross talk. It also helps to reduce the magnetic field's effect on other pairs. Cables with more twists per foot offer the best performance and are normally more expensive. The foil shielding that surrounds the twisted pairs blocks sources of interference from electronic noise outside of the cable in addition to keeping stray noise from escaping to the outside world. STP is often the choice of transmission media when heavy electrical or electronic equipment exists near cable runs. It may also be used to increase network security by reducing the amount of outside signal radiation that could be intercepted by inductive signal equipment used by someone trying to intercept sensitive network communications.

Figure 11: Unshielded twisted-pair (UTP) cable

The outer sheath exists to protect the inner components of the cable. Like many cables, twisted-pair jackets are made of some form of PVC or special plenum sheaths that are used in applications that require nontoxic and fire-resistant cable.

UTP is basically the same as STP except that it does not have a foil shield (see Figure 11). Without the shield, it is more prone to cross talk and other forms of interference, although some cross talk is reduced because of the twists in the pairs of wire.

UTP is probably the most popular cable type for networks today. The Electronic Industries Alliance (EIA) and the Telecommunications Industries Association (TIA), with the endorsement of the American National Standards Institute (ANSI), have defined several categories of UTP cable for different applications (Network Magazine 1999; Fogle 1995; Tittel and Johnson 2001). Category 1 is traditionally used for telephone and voice transmissions. Category 2 is capable of data transmissions as high as 4 Mbps. Category 3 is certified for up to 10 Mbps for 10BaseT Ethernet and suitable for 4-Mbps token ring. New technology applications, including 100BaseT4 and 100Base-VG AnyLAN, can utilize this lower rated cable for 100-Mbps bandwidth. Category 4 can handle up to 16 Mbps, which includes token ring 16 Mbps and 10-Mbps Ethernet applications. Category 5 cable type supports bandwidths of as much as 100 Mbps.

At the turn of the century, a new enhanced category 5 (CAT5E) cable was introduced that boosted the performance limits of the original category 5 cables. These improvements include further reduction in signal attenuation and cross talk, and they also provide problem-free full duplex transmissions.

Up to this point, we have used the term *bandwidth* to describe the speed at which data travels on the transmission media. In reality, two factors are involved in the

speed of data transmissions: bandwidth and data rates. A more precise definition for bandwidth would be the carrying capacity of a signal, which is typically measured in megahertz (Mhz). A good illustration of this would be like a highway. Some highways consist of only two lanes, where others may consist of ten or more lanes. The more lanes a highway has, the better the traffic flow. Thus, the higher the bandwidth rating of a cable, the more data traffic it can handle (Kish 1998).

The data-rate measure is simply the amount of data that passes through the transmission media in a given period of time, which is measured in bits per second (bps). The data rate is directly influenced by the amount of data being transmitted and the bandwidth of the media, just as the traffic flow on a highway will be influenced by the number of lanes and the number cars that need to use that highway to get to their destinations (Kish 1998).

The bandwidth capacity of a cable has been specified in cables prior to CAT5, but it did not seem to be as much of a factor until now when bandwidth is everything with today's electronic superhighways. Both category 5 and 5E cables specify 100-Mhz bandwidth signals. Without getting into the specific details of calculating the data rates of CAT5 and CAT5E, it suffices to say that these cables are being pushed to their limits when trying to achieve 1 Gb/sec transmission rates, which is becoming the data-rate standard today for LAN interconnect speeds.

In 2002, a category 6 cable was introduced that offers higher performance specs along with a greater bandwidth of 250 Mhz. CAT6 cabling systems are better able to meet the bandwidth demands associated with 1 and 10 Gb/sec requirements that are typical with today's LANs. To take advantage of the more stringent specifications of the CAT6 cable, installations must incorporate jacks, patch cables, and panels that meet the CAT6 requirements. Mixing older CAT5 components with CAT6 cabling would bring the overall cable infrastructure down to CAT5 standards.

On the horizon, the proposed category 7 cable will support bandwidths up to 600 Mhz and further reduce cross talk and signal loss. CAT7 cable will also incorporate newly designed cable connection components including jacks and patch panels that will function better at the higher frequencies. The overall trend in twisted-pair cabling standards focus on increasing performance and stability at higher frequencies (bandwidths) (Black Box Explains 2005; Global Technologies 2002; Kish 1998).

Twisted-Pair Cable Network Applications

Twisted-pair cable uses a special modular connector for categories up to and including CAT6. Standard telephone wire uses a four-connection plug called an RJ-11. For network applications, an eight-connector RJ-45 is used (see Figure 12). UTP wire pairs often consist of a solid core with a thin layer of insulation. The installation of RJ-45 connectors, called *insulation displacement connectors* (IDCs), requires a special crimping tool that pushes the connector into the insulated wire. When each connector is pushed into the wire, the insulation is pierced just enough to make contact with the center core of the wire (Spurgeon 2000).

Figure 12: RJ-45 connector

Figure 13: RJ-45 connection to a network interface card

Twisted-pair cable is typically used for point-to-point wiring, such as with star topology configurations. UTP is connected to a network device via a NIC's RJ-45 jack (see Figure 13), with the other end connected to a hub, switch, or router. In some cases, a patch panel or punch-down block may be used to better organize cabling before it is attached to the devices.

There are several IEEE Ethernet standards for twisted-pair media. The most documented are the 10BaseT, 100BaseT, and 1000BaseT standards (see Table 3). All twisted-pair Ethernet standards require a maximum cable length of 100 m and use star topology, which allows only one network connection for each cable segment. Note that this is considerably less than the coaxial cable specifications. It is much more difficult to control high-frequency signals over twisted-pair; thus, shorter cable runs are used to cut down on the effects of a harsher electrical environment (Spurgeon 2000). The major differences between 10BaseT, 100BaseT, and 1000BaseT are their data rates: 10, 100, and 1000 Mbps, respectively.

Each IEEE specification describes which wire type is most suitable for a particular application. Category 3 cable is adequate for 10BaseT applications. In fact, only two of the four pairs of wire are actually used. The 100BaseT standard is a bit more complicated. There are three cable

Table 3: Ethernet Twisted-Pair Cable Specifications

Characteristic	Specification
Maximum cable segment length	100 m
Maximum number of devices per segment	1
Bandwidth	
10BaseT	10 Mbps
100BaseT4, 100BaseTX	100 Mbps
1000BaseT	1,000 Mbps
Topology	Star
Cable access method	CSMA/CD

configurations for the 100BaseT standard: 100BaseT4, 100BaseTX, and 100BaseFX. 100BaseT4 can produce 100-Mbps bandwidth using all four pairs of category 3, 4, 5, 5E, and 6 cables. With 100BaseTX, only two pairs of category 5, 5E, or 6 cables are used to transmit and receive at 100 Mbps. 100BaseFX is the fiber-optic extension for 100BaseT. 100BaseT is often referred to as Fast Ethernet.

One of the newest technologies, Gigabit Ethernet, transmits 250 Mbps over each of the four pairs of category 5E or 6 wires simultaneously for a total bandwidth of 1 Gbps. Gigabit Ethernet is ideal for network backbones that connect network switches and hubs together. Many are now talking about 10-Gigabit Ethernet, which is in its early stages of development and implementation. Currently, the IEEE specification for 10-Gigabit Ethernet is for the use of fiber-optic cable, but development for a copper-based standard is underway and predicted to be completed within the next few years. Once a twisted-pair specification comes to fruition, the cost for this super high-speed Ethernet standard will be greatly reduced (10 Gigabit Ethernet Alliance 1999, 2002; Tittel and Johnson 2001; Violino 2003).

Ethernet standards for UTP follow TIA/EIA 568 standards. Wire pairs within a particular category of cable are color coded. The preferred 568 standard dictates that wire pairs will consist of a green wire paired with a white wire with a green stripe, an orange wire paired with a white wire with an orange stripe, a blue wire paired with a white wire with a blue stripe, and a brown wire paired with a white wire with a brown stripe. Each pair will be attached to a specific connection on the RJ-45 connector (see Figure 14). *Tip* and *ring* are used to identify the connections made by each pair. These terms come from the old telephone systems, which required a patch cable to connect one telephone line to another. The connector on the patch cable consisted of a tip at the end and a ring separated by an insulator that separated the two conductors. These two conductors provided the path for transmitting or receiving communications. Traditional analog telephone lines require only one pair for operation. Network transmissions typically require two or four pairs. Note the earlier discussion regarding the required pairs for each of the Ethernet standards 10BaseT, 100BaseT, and 1000BaseT (Spurgeon 2000).

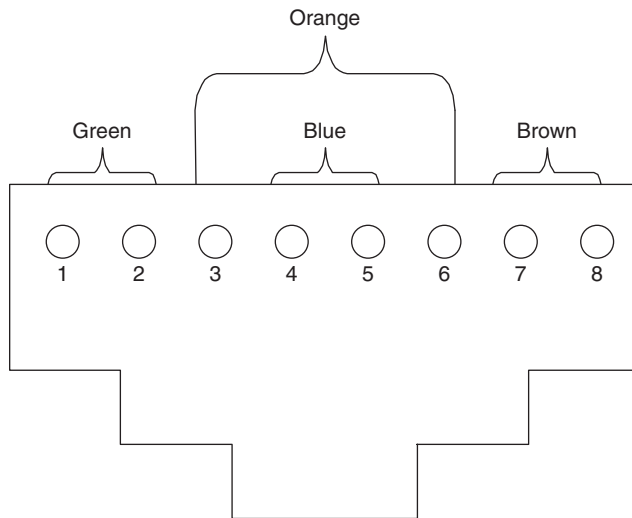

Figure 14: T568A wiring scheme

The majority of network device connections using UTP use *straight-through wiring*, which means that both ends of the RJ-45 connector are wired exactly the same way. Each pair of cables either transmits or receives data. Likewise, each NIC transmits data through certain connections and receives through others via its RJ-45 port. If a straight cable was connected to two NIC ports, then the result would be that the transmit connections of both ports would be connected to each other, as would the receive links. It should be apparent that when one NIC transmitted, the other would not receive it because of the direct connections between the ports. Therefore, there must be some kind of crossover that makes a connection between the transmit and the receive pairs. In reality, most network connections between devices are made via hubs or switches. These devices provide the crossover for the transmit and receive pairs.

For some applications, a special *crossover cable* is required. A crossover cable is made by crossing pairs two and three on the opposite end of the connecting cable. This allows two network devices to be connected independently without using a hub or other central wiring point. For example, if a small office with two computers wanted to network, it could build or buy a crossover cable and connect the NICs from both computers together to form a small network without the expense of a hub. Crossover cables are also used to connect hubs or switches together if they are not supplied with an *uplink port*. Uplink ports are optional ports that take care of uncrossing the links between these centralized wiring points.

In comparison, there are several advantages and disadvantages to twisted-pair and coaxial cabling. Coax appears to have the distance contest won but is losing the bandwidth race. During the mid- to late 1980s, coax was the wire of choice, but now twisted-pair seems to be the predominate cable used for most LAN interconnections. Twisted-pair cable offers great flexibility within network design and layout in addition to its lower cost for material and installation. Even though maximum cable runs are shorter than coax, 100 m is still a significant distance

Table 4: Token-Ring Cable Specifications

Characteristic	Specification
Maximum cable segment length	101 m (type 1) 45 m (type 3) 100 m (cat 3) 225 m (cat 5) 400 m (STP)
IEEE specification	802.5
Bandwidth	4, 16, or 100 Mbps
Topology	Star-wired ring
Cable access method	Token passing

for most network connections. With applications being developed to use the newest categories of UTP—CAT6 and CAT7—the potential advances for twisted-pair cable are encouraging with regard to increased bandwidth and expanded connection options.

Token-Ring Cabling

In the mid-1980s, IBM developed the token-ring architecture that used a special type of twisted-pair wiring. IBM engineered a cabling system that included nine cable types, numbered from one to nine. These cable types included STP, UTP, and fiber-optic media. For token-ring networks, types 1 (STP) and 3 (UTP) were the most prevalent. Type 1 cable allowed for lengths of up to 101 m, with a maximum data rate of 16 Mbps. Because of its lack of shielding, type 3 cable runs were limited to 45 m and a data rate of 4 Mbps (Tittel and Johnson 2001). Today, most token-ring applications use UTP category 3 or 5 cable with RJ-45 connectors. As noted in Table 4, there have been some improvements in cable lengths with the use of these media (Feit 2000).

The IEEE specification for token ring is 802.5, which describes the data rate of 4 or 16 Mbps using the token-passing cable access method. In 1999, *high-speed token ring* (HSTR) introduced an improved bandwidth that resulted in a data rate of 100 Mbps with twisted-pair or fiber-optic cable. Token ring uses a star-wired ring topology (see Figure 6). Fault tolerance is probably the biggest advantage the token-ring architecture has to offer because of the logical continuous ring that is created when using the IBM cabling system along with the star-wired ring topology that provides a dual path for data transmission. Theoretically, if a cable is cut, the token-ring network can continue to operate because of the redundant path. Another plus is the use of the token-passing access method, which eliminates collisions (Dean 2003; Feit 2000; Tittel and Johnson 2001).

FIBER-OPTIC CABLE

The bandwidth capacities of coax and twisted pair are dwarfed by that of fiber-optic cable. Consider that the capacity of a simple telephone line to carry data is equivalent

to the flow of liquid through a drinking straw. It would take a tunnel large enough to drive a bus through to equal the bandwidth of a single fiber-optic strand using today's technologies. Furthermore, if technology existed to fully utilize fiber-optic capabilities, then it would take a tunnel the diameter of the moon to handle the flow of liquid equal to its potential bandwidth (Jamison 2001).

Fiber-optic cable carries optical pulses rather than electrical signals, which eliminates any possible electrical interference. All types of conducted communication media are vulnerable to electronic eavesdropping to some degree, but fiber-optic cable is less prone to eavesdropping because its signal does not radiate outside of the media as does copper-based wire. Therefore, the only way to intercept data from fiber-optic cable would be to tap into it, which would require a great deal of effort and skill.

Fiber-optic cable lengths are measured in kilometers rather than meters, which greatly reduces the number of signal-repeating devices required for long-distance cable runs. One of the most impressive characteristics is the high volumes of data that can be pumped through optical fibers. All this makes fiber-optic cable the medium of choice for many WAN applications, where network traffic can cause major bottlenecks (Tittel and Johnson 2001). In addition, many people believe that fiber-optic cables may become the norm rather than the exception for interconnecting network devices on a LAN (Kostal 2001; Sinks and Balch 2001; Vickers 2001).

Components

Fiber-optic cable consists of three components: a fiber core, cladding, and a protective outer sheath. The *inner core* is either glass or plastic fiber. Plastic is used when a flexible cable is needed; however, plastic cable is more susceptible to attenuation than glass, which limits the length of the cable. *Cladding* provides a coating that keeps the light waves within the fiber. The outer *protective jacket* is used to protect the fiber inside (Tittel and Johnson 2001).

Fiber Modes

Fiber-optic cable comes in two forms: single and multiple mode. Single-mode fiber is best for applications that require great distances. This fiber is narrow and requires an extremely focused source of data transmission that can keep the light waves on a straight, continuous path. The narrow internal core makes room for one-way traffic only. This reduces obstacles (stray light) that might interfere with the delivery of packets, resulting in more

reliable transmissions over longer distances. A laser is normally used as the generating source for single-mode transmissions because it can produce the narrow band of light needed (Jamison 2001).

Multimode fiber (MMF) is less expensive than single-mode because its transmission devices consist of light-emitting diodes (LEDs), which are not as costly as laser sources. MMF fibers also have a larger core than single mode. A wider core helps to compensate for information loss because of light dispersion when using less precise light-emitting sources. A larger core allows the light wave to bounce around, which results in shorter transmission distances. The connections to the fiber are easier to make to the larger core, however. MMF is ideal for shorter cable runs within single buildings for LAN backbones (Jamison 2001).

Fiber-Optic Cable Network Applications

There are four major types of fiber connectors: *straight* (ST), *straight connection* (SC), *medium interface connector* (MIC), and *subminiature type A* (SMA) (see Figure 15). ST is often used for interconnections between individual fibers and optical devices. When joining optical fibers, an SC connector may be used. This connector consists of connections for two fibers: one for receiving and the other for sending. MIC connectors are one-piece connectors similar to the SC used to connect both the transmit and the receive fibers. It is primarily used with the *fiber distributed data interface* (FDDI) protocol. As with the ST connector, SMA uses individual connectors for each fiber. The major difference is that SMA uses either a straight or a stepped ferrule to ensure a precise fit, whereas the ST connector uses a bayonet twist-lock connection (Tittel and Johnson 2001).

The major differences between fiber-optic and other cable types are fiber optics' long-distance cable runs and high bandwidth. For example, the maximum fiber length for the 100BaseFX Ethernet standard is 2000 m, and the data rate for 1000BaseSX tops out at 2000 Mbps. More recently, the 10GBaseSR, 10GBaseLR, and 10GBaseER standard reach 10,000 Mbps. These specifications easily exceed other cable specifications. The potential of fiber-optic cable is limited by the technology that exists today. As the cost of fiber declines and the advances in transmission devices continue to improve, the use and performance of fiber will continue to grow.

In some applications, fiber optic is not needed for its high bandwidth but to facilitate long cable lengths or to block unwanted electrical interference. For example, the

Figure 15: Fiber-optic cable with connectors

Table 5: Fiber-Optic Cable Specifications

Characteristic	Specification
Maximum cable segment length	2000–40,000 m
IEEE specification	802.3
Bandwidth	100–10,000 Mbps
Topology	Star
Cable access method	CSMA/CD

100BaseFX specification supports the use of fiber-optic cable. With the exception of distance, the other specifications for 100BaseFX are essentially the same as that described for UTP cabling (see Table 5). Token ring also has a cable specification for the use of fiber optic for connecting its MAUs. Again, this does not fully utilize fiber optic's full bandwidth potential, but it allows for longer cable runs.

Fiber-optic applications do not stop at 100 Mbps. Gigabit Ethernet, 1000BaseLX and 1000BaseSX each sport data rates of 1000 Mbps. The major difference in these two standards is the type of laser used. 1000BaseLX uses a long-wavelength laser that can transmit a signal over 5000 m of fiber in full duplex mode. A short-wavelength laser is used in 1000BaseSX applications that support a maximum cable length of 550 m and 2000 Mbps data rates in full duplex mode. Still in its early stages, 10-Gigabit Ethernet is sure to accelerate the use of fiber-optic cable into the future (10 Gigabit Ethernet Alliance 2002; Tittel and Johnson 2001).

The only thing holding fiber-optic transmission rates at bay is the devices used to drive the signals through the fibers. As noted at the beginning of this section, the potential of fiber-optic media is truly enormous. Currently, the primary application for fiber-optic cabling is for long connections and network backbones. There are some limited applications of direct connections between individual computers and hubs, but many people feel that this will increase over time as equipment and installation costs continue to decrease.

COMPARISONS AND CONTRASTS

When comparing and contrasting the advantages and disadvantages of the various types of cables, the particular

application must be considered. It may be true that fiber-optic cable has the potential to transmit data at much faster rates than UTP, but if bandwidth is not an issue, then the added complexity involved in installing fiber optic where it is not needed would make it a bad choice. Table 6 compares and contrasts each cable type discussed in this chapter, showing more clearly how a particular cable may be applied (Tittel and Johnson 2001).

No hard and fast rules govern cable selection. Each business or industry must evaluate and determine its specific cabling needs. From the discussion in this chapter, it should be fairly obvious that the use of coaxial cable is fading, which means that plans for new network installation would best avoid using coax. This will help narrow down cable selection to twisted-pair, fiber-optic cable, or both. The physical size, number of devices, and distances between devices will also inform planning decisions.

MEDIA SECURITY

When designing a network infrastructure, the security of conductive communications media should be a strong consideration in the overall network design. Most common security breaches are the result of someone hacking into an organization's network through security holes in user-authentication policies or vulnerabilities in network operating systems from far distances. Security flaws of this order seem to upstage the potential risks associated with the physical security of network devices and cabling, but these risks do exist. For example, a network's infrastructure could be at risk if the physical cable routes are not carefully thought out. The physical path of a cable must be secure to prevent someone from tapping into the network, which would result in an unauthorized connection. Also, connecting devices such as hubs or switches placed on the floor or up in a crawl space in a common area of a building may pose a security risk.

As noted earlier, the physical location of the network cabling has the potential to create a security risk if not protected. Copper cabling, such as coax and twisted-pair, are probably the most vulnerable because of the simplicity of splicing into an exposed cable. Areas of special concern would be the cable routes that run through or above common areas of a building, along with cables that are run outside of the building or underground. In many ways, tapping into a computer network by an unauthorized cable tap may make a network more vulnerable to attacks than from external security threats. If access is gained via

Table 6: Comparison of Cable Types

Cable	Bandwidth	Length	Interference	Installation	Cost
Thinwire coax	10 Mbps	185 m	Moderate	Easy	Low
Thickwire coax	10 Mbps	500 m	Low	Hard	High
UTP	100 Mbps	100 m	High	Easy	Low
STP	1000 Mbps	100 m	Moderate	Moderate	Moderate
Fiber-optic	10 Gbps	100 km	None	hard	Very high

a wire tap to the internal network infrastructure, external security measures such as firewalls would provide no protection. Also with direct access to the LAN, a person might be able to use eavesdropping or sniffing utilities to access security devices and reconfigure them to allow external access. Once a security device has been reconfigured, sensitive company data (such as product design secrets, customer information, and financial data) might be lost or stolen (Campbell, Calvert, and Boswell 2003).

Another risk involving communications media security is electronic eavesdropping. Cable that uses a copper-type conductor can be vulnerable because of the electromagnetic emissions it produces. With the right type of equipment, sensitive network traffic could be intercepted. Twisted-pair cables used in Ethernet applications are most likely targets for electronic eavesdropping because most of these cables are not shielded. This type of threat is often hard to combat if a network is constructed using nonshielded wire.

Once the potential physical security threats have been identified, it is fairly simple to eliminate many of these concerns. With regard to wiretaps, network designs should make sure that all cable runs are not exposed to unsecured areas. In cases in which cables must be routed in public areas or outside of buildings, copper-based media should be replaced with fiber-optic cable, which is difficult to tap. Several options of protection are available for electronic eavesdropping. One is to reduce electromagnetic emissions by using a shielded twisted-pair cable. Another, although expensive, option would be to replace copper-type transmission media with fiber-optic cables, which would eliminate any possible electronic emissions. Of course it would be expensive to use fiber throughout an entire network. A final alternative, which is orthogonal to transmission media decisions, would be to encrypt any sensitive company information before it is transmitted over the communication lines (Campbell, Calvert, and Boswell 2003).

Threats to a network's physical transmission media are real and need to be considered in all infrastructure designs. In most cases, it is not expensive for an organization to protect its network from wiretaps and eavesdropping. Business and industry need to consider the possible holes in physical security and plan cable runs and use cable types that will reduce or eliminate the possible risks to the internal network. In addition, using encryption for sensitive data transmissions should protect against any breach of security with regard to electronic eavesdropping.

CONCLUSION

Conductive transmission cables provide the highway for data communications. This chapter has discussed the most popular types of cable in use today. As times change, the applications and uses for these various cable types will change. Some limiting factors for conductive transmission media are cable attenuation and the devices that drive the information through them such as NICs, hubs, and switches. We saw that data rates for twisted-pair cable have increased from approximately 1 to 1,000 Mbps over the past twenty years. Transmission speeds over fiber-optic cable are only now being realized. What are

the limits? What does the future hold for conductive transmission cables? How do wireless technologies fit into network communications? No one knows the answers to these questions, but at least the questions are being asked, so researchers can continue to experiment and produce new applications for all transmission options.

GLOSSARY

Bandwidth: The maximum range of frequencies a communications medium can carry.

Baseband: A digital transmission signal that uses a single channel to communicate with devices on a network.

Broadband: An analog transmission that carries multiple digital signals over multiple channels.

Cross talk: An electromagnetic field surrounding certain types of cable that may interfere with adjacent wires.

Hub: A central wiring point for network devices configured in a star topology. Its purpose is to repeat the broadcast packets to all connected nodes.

Impedance: The resistance of conducted communications media to a transmitted signal.

Insertion loss: The loss or attenuation of a signal that occurs each time a device is inserted into a network using conductive communications media.

Local area network (LAN): A collection of computers connected to a network within a single floor or building.

Network interface card (NIC): An electronic device that is installed in a network node that provides a link to the network media.

Node: Any device connected directly to a network.

Packet: An entity that contains data plus other information (such as destination, origination, and error-checking bits) and is transmitted over a network.

Protocol: A set of rules that specify how communicating entities will format data and process events.

Signal attenuation: The loss of signal strength as data travels the length of the cable that is caused by the cable, connectors, or other devices on the conducted communication medium.

Terminator: A device attached to a cable configured with a bus topology that eliminates signal bounce.

Topology: The physical cabling configuration of a network.

INTRODUCTION

The current popularity of wireless communication system is driven mainly by the commercial success of the second-generation digital mobile wireless standards, as well as the technological advances in device implementations and sophisticated signal-processing algorithms. With the continued growth of mobile radio communications, the study of radio wave propagation is even more important in determining system parameters and facilitating design and development. Future generation wireless systems are no longer used to transmit voice only but instead transmit large multimedia data. Currently, the demand for very high data rate Internet access for mobile users and the desire for multimedia services through the Internet with seamless connectivity is driving the need to design high-speed reliable wireless communication systems. Characteristics such as bandwidth on demand capability, global roaming, and interoperability are desirable. However, to achieve these improvements, accurate characterization and modeling of the channel is essential. Hence, the importance of developing effective propagation models for wireless communication systems cannot be overemphasized.

The goal of this chapter is to present a tutorial on wireless channels in general by examining the fundamental terminology, definitions, concepts, and modeling techniques. First, we introduce the concept of radio wave propagation, which is fundamental in any wireless communication system. Then the losses associated with large-scale propagation and their mechanisms are characterized. This is followed by examining the channel-modeling techniques for small-scale fading effects, and the characterization of the fading environment in a wireless channel.

RADIO WAVE PROPAGATION

Propagation is the process of wave motion from the *transmitter* (Tx) to the *receiver* (Rx). During propagation, the signal amplitude may be attenuated. The signal may also be subjected to *time variability* (signal strength and quality varies with time), *space variability* (signal strength and quality varies with location and distance), and *frequency variability* (signal strength and quality differs on different frequencies). This implies that the transmitted signal in the channel is attenuated, delayed, and phase-distorted, with noise and possibly interference added, thereby presenting fundamental limitation on the system *quality of service* (QoS). Because of the limitation of the channels, sophisticated signal design, transmission, and reception schemes are required to maintain reliable communication.

Before we can design better wireless communication systems, we must thoroughly understand the characteristics of the channel because it imposes limitations on the quality of the transmission. Because of this, wireless systems engineers are now more interested in understanding and predicting radio wave propagation characteristics in various environments (urban, suburban, indoor, etc.). For example, the study of propagation is used to determine where base stations should be placed, what transmission powers should be used, what radio channel is to be assigned to a cell, and what types of handoff decision strategies or algorithms are to be used. To design an efficient wireless communication system, it is important to understand how a radio frequency (RF) signal is transformed from the time it leaves a Tx to the time it reaches the Rx. The various mechanisms of radio wave propagation are summarized in this section.

Figure 1: Illustration of free space LOS propagation

Free Space Propagation

By definition, *free space* (FS) is a region of space in which there are no obstacles to get in the way, no gases to absorb energy, and nothing to scatter radio waves. Free space is essentially a vacuum by definition. When a radio wave propagates in free space, it is the approximation to “ideal” propagation in which other mechanisms of propagation (discussed below) are not present or significant. It is simply a mode of propagation that requires a direct *line of sight* (LOS) for the radio waves to propagate between the Tx and Rx, unobstructed via a single path. In FS propagation, a radiated radio wave from a Tx in a given direction will ideally propagate outward from the Tx towards the Rx in a straight line traveling at the speed of light. Free space propagation involving direct LOS is illustrated in Figure 1. This mode of propagation is present in many terrestrial microwave and satellite communication systems.

Radio LOS is a necessary but not sufficient requirement to obtain FS propagation. The first *Fresnel zone* clearance is also needed (SoftWright 1999). The first Fresnel zone illustrated in Figure 2, for directional antennae, describes that portion of the radio wave path in which there are no obstacles. It is an ellipsoidal region surrounding the direct beam between the Tx and the Rx antennae. Additional Fresnel zones (second, third, etc.) may contain some level of obstacles that exist beyond the boundaries of the first Fresnel zone. Microwave systems using waveguides and parabolic antennae have approximately one-half the total transmitted energy in the first Fresnel zone, which accounts for some 25 percent of the total

received energy. Microwaves passing an obstacle such as a hilltop, a building, or a tree may have part of their strength obstructed, thereby decreasing the signal level at the receiving antenna. Thus, full path clearance is desired for LOS and free space propagation. If at all possible, an LOS microwave path should be laid out with first Fresnel zone clearance.

Suppose that the source of the radio wave is from an isotropic antenna (i.e., a source radiating equally in all directions). The total energy is uniformly spread out over a spherical area around the source. In practice, it is of interest to know the received power, P_r , relative to an isotropic radiator at a distance d or simply how much energy gets from the transmit antenna to the receive antenna. This power is simply the incident power flux density, S_{inc} , multiplied by the effective capture area (or aperture) of the antenna, A_{eff} , such that

$$\begin{aligned} P_r &= S_{inc} \times A_{eff} \\ &= \left(\frac{P_t G_t}{4\pi d^2} \right) \times \left(\frac{G_r \lambda^2}{4\pi} \right) = P_t G_t G_r \left(\frac{\lambda}{4\pi d} \right)^2 \\ &= EIRP \times G_r \left(\frac{\lambda}{4\pi d} \right)^2 \text{ watts,} \end{aligned} \quad (1)$$

where P_t is the transmit power output, G_t is the transmit antenna gain, G_r is the receive antenna gain, λ is the wavelength, and $EIRP = G_t P_t$ is the *effective isotropic radiated power* (EIRP).

Equation 1 is the well known Friis equation, which represents the ideal received signal assuming no loss in the channel. It is evident from Equation 1 that as the propagation distance increases, the radiated energy is spread out over a larger distance d such that the received power decreases in proportion to d^2 or at the rate of 20 dB per decade.

Mechanism of Radio Wave Propagation

Beside the idealistic FS propagation, there are other propagation mechanisms such as reflection, refraction, diffraction, scattering, and absorption. A brief overview of these mechanisms is presented below.

Reflection

Reflection occurs when a radio wave strikes an object with larger dimensions compared to its wavelength. The part

Figure 2: Fresnel zone clearance between transmitter and receiver

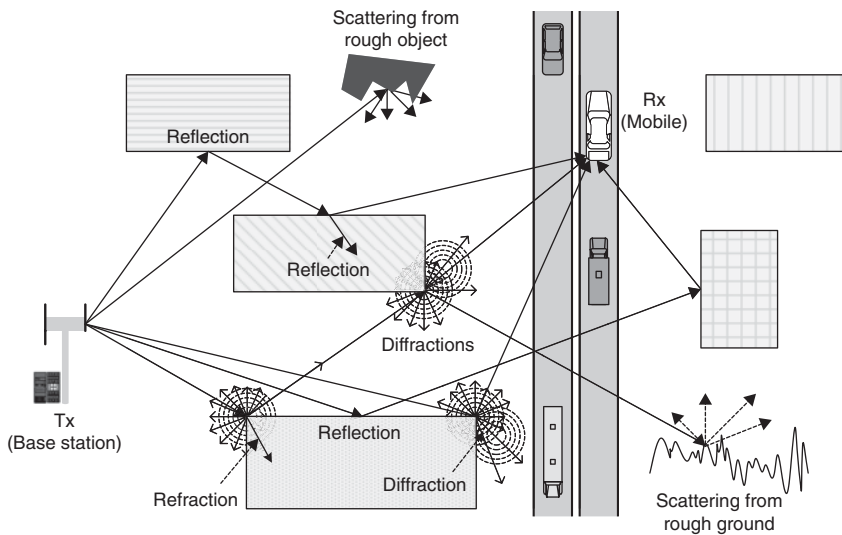

Figure 3: Illustration of the wireless propagation mechanisms *reflection, diffraction, refraction, and scattering*

of the wave that is not reflected back loses some of its energy by being absorbed into the material; the remaining wave passes through the reflecting object. All radio waves will undergo some level of reflection if the propagation wave encounters abrupt changes in the physical medium (see Figure 3). The more abrupt the discontinuity, the more pronounced the reflection; depending on the type of material, the RF energy can be partially reflected, fully reflected, or absorbed. From the properties of the two media, one could compute the amount of reflection. If the incident object is a good conductor, then the wave is totally reflected with angle of incidence the same as angle of reflection. Reflecting rays from different surfaces may interfere constructively or destructively at the receiver. In microwave systems, the waves usually reflect from ground and surrounding objects, producing multiple-ray paths between the Tx and the Rx, a phenomenon known as the *multipath propagation*.

Refraction

Refraction is the bending of radio waves. A radio wave can be refracted or bent if it is transmitted into ionized layers (e.g., the atmosphere) or at the boundary between two dielectrics. When the incident wave propagates into another medium at an angle, refraction occurs. When radio waves propagate from a medium of one density to a medium of another density, the speed of the wave changes, causing the waves to bend at the boundary of the two media and toward the denser medium or where the radio wave's velocity is the least. For example, in the atmosphere, as the wave enters the denser layer of charged ions, its upper portion moves faster than its lower portion, causing the abrupt speed increase at the upper layer and thereby causing the wave to bend back toward the Earth. The amount of refraction a radio wave undergoes depends on the ionization density of the layers, the frequency of the radio wave, the angle at which the radio wave enters the layer, and the physical characteristics or refractive index of the medium.

Diffraction

The mechanism of *diffraction* occurs when a radio wave encounters some obstruction along its path and tends to propagate around the edges and corners and behind the obstruction. Each time a radio wave passes an edge such as a corner of a building, it bends around the edge and continues to propagate into the area shadowed by the object. This is illustrated in Figure 3, where the arrows are used to indicate the direction of propagation and how the signal reaches the areas around the corner because of sources of secondary waves situated at the corner of the obstacle. The more the waves have to bend around a corner, the more they lose their energy. The areas to which the rays have to bend more gain relatively less additional field strength than the areas to which the rays can proceed almost linearly. The field strength of the secondary waves is much smaller than that of the primary wave. In practice, the diffracted waves can be neglected if there is a LOS between the Tx and the Rx. The height or dimension of the obstruction affects the amount of diffraction at the wavelength of the transmission. The same obstruction height may produce lower diffraction loss at higher λ than at lower λ . Radio waves with long wavelengths compared to the diameter of an obstruction are easily propagated around the obstruction. As the wavelength decreases, the obstruction causes more and more attenuation until, at extremely high frequencies, a definite shadow zone develops.

Scattering

Waves are attenuated through molecular absorption in a way similar to sound waves being absorbed in the wall between two adjacent rooms. It is the result of small objects and irregularities in the channel, rough incident surfaces, or particles in the atmosphere. It occurs when the radio wave encounters objects with dimensions that are on the order of or smaller than the propagating wavelength; this causes the signal to spread in all directions. *Scattering*, as in diffraction, causes energy to be radiated in many different directions, and the amount of scattering

depends on the surface roughness of the scattering object. Scattering has been proven to be one of the most difficult mechanisms to model, and its theoretical prediction is also more complicated to analyze. Scattering can be neglected in many practical cases compared to other mechanisms such as diffraction, reflection, and combinations of reflections and diffractions.

Absorption

Absorption describes the process of radio energy penetrating a material or substance and being converted to heat. When radio waves propagate in the atmosphere and in higher degree materials such as glass, concrete, and wood, RF energy can be absorbed. Two cases of absorption of radio waves are prevalent. One occurs when radio waves are incident on a lossy medium, and the other results from atmospheric effects. When a radio wave strikes an object, the incident wave propagates into the lossy medium and the radio energy experiences exponential decay with distance as it travels into the material. The wave is either totally dissipated or will reemerge from the material with smaller amplitude and continue to propagate. Particles in the atmosphere also absorb RF energy. Absorption through the atmosphere depends on weather conditions such as humidity, drizzle, heavy rain, fog, snow, and hail. Absorption of RF energy through the atmosphere is not significant and may be ignored at frequencies below 10 GHz.

Multipath Propagation

The term *multipath* is simply used to describe the multiple propagation paths of a radio wave as it travels from the Tx to the Rx. *Multipath propagation* (MP) is the result of the collective effect of the different propagation mechanisms discussed above. In other words, when all of the different propagation mechanisms are significant, it is more likely that the radio wave may take multiple paths as it propagates from the Tx to the Rx.

An illustration of multipath propagation is shown in Figures 3 and 4. In Figure 3, the mobile unit receives multiple radio waves from the fixed base station (BS). As the mobile unit moves, the wireless channel's characteristics change and may impact adversely on the quality of the received signal. In Figure 4, a radio wave transmitted from the transmitter denoted as Tx can get to the receivers through many paths. Observe that four waves are received by receiver 1 (denoted as Rx₁). One path is the direct wave from Tx to Rx₁. Another path is the basic ground reflected wave (Tx–A–Rx₁). The third wave is reflected, diffracted, or both from a surrounding object B. Waves can also refract and diffract from the atmospheric layers to a receiver (e.g., Tx–C–Rx₁). So at Rx₁, the received signal is a combination of the direct, ground, reflected, and refracted radio waves that constitute the multipath components. These waves, having traveled different paths, arrive at the receiver Rx₁ at different times, with different amplitudes, and possibly with different phases. A similar situation can occur at receivers Rx₂, Rx₃, Rx₄, and Rx₅, depending on the distance and location. Receivers at Rx₃ and Rx₄ may experience waves with greater angle of incidence, delay, and multiple refractions from the atmospheric layers.

Radio waves that are received in phase reinforce each other and produce a stronger signal at the receiver; while those that are received out of phase produce weak or faded signal. Small alterations in the transmission path may change the phase relationship of the waves, causing periodic fading. In other words, multipath propagation leads to the phenomenon of *multipath fading* discussed later in this chapter. Because the multipath radio waves are attenuated differently and arrive with different path gains, time delays, and phases, they can interfere with the direct rays or with one another, causing significant fluctuations and hence degradation in the system performance. The resultant signal may vary widely in amplitude and phase, depending on the distribution of intensity and relative propagation time and bandwidth of the transmitted signal. If the Rx is a mobile unit, then the number of

Figure 4: Multipath propagation consisting of several modes and mechanisms of propagation

paths may change drastically when the mobile changes its position or when the number of intervening obstacles increase or decrease.

Indoor Propagation

The use of wireless systems indoors introduces one of the biggest design challenges in communication systems. Since the advent of the IEEE 802.11 standard in 1997, the number and the use of *wireless local area networks* (WLANs) has continued to grow in popularity. WLAN-capable devices can now be found in laptops, desktops, personal digital assistants, gaming systems, and even *voice over Internet protocol* (VoIP) phones. These networks are primarily targeted for indoor use and are most often based on either the IEEE 802.11-type protocols using the unlicensed bands at 2.4–2.5 GHz or 5.15–5.85 GHz. Because of the popularity of these devices, lately more interest has been paid to the properties of indoor wireless channels.

Indoor propagation is somewhat different from the outdoor propagation environment, although it is characterized by the same propagation mechanisms. However, the influence and variability of the environment is much stronger indoors because the propagation distances covered are much smaller. Indoor propagation is affected by building layout (e.g., number of walls), construction materials, building type, the locations of transceivers or access points, as well as the propagating wavelength. Walls and obstacles made of different materials obstruct RF energy differently. The position and type of antenna mounting strongly influence the propagation (e.g. antennae mounted at the desk level, on the ceiling, or on the wall). In general, indoor channels may be classified as either LOS or obstructed with varying degrees of clutter. Detail presentation on the indoor propagation can be found in Hashemi (1993).

CHANNEL MODELING

Modeling the radio channel has always been one of the most difficult parts of wireless system design. Before wireless communication systems can be designed and deployed, accurate propagation characteristics of the environment are required. A variety of propagation models are available for approximating the channel characteristics. These models provide some insight into the effects of different channel characteristics on wireless communication systems. Some of the characteristics are determined analytically, and some are modeled statistically using measured propagation data. Measurements have been performed to obtain propagation loss information and signal-power variations for conventional radio communication systems (Anderson, Rappaport, and Yoshia 1995; Fleury and Leuthold 1996; Molkdar 1991). These measurements and studies have shown that, in general, radio wave propagation in the wireless channel can be decomposed into three components (Rappaport 2002; Prasad 1998):

1. Large-scale propagation path loss models that indicate the dependency of the mean power of the received signal to the distance d between the Tx and the Rx. These

models assume that the propagation is fairly constant over a large area and the signal is slowly time-varying. These models are used to (a) predict the mean signal strength between the Tx and the Rx for arbitrary d , (b) characterize the signal strength over large distances, (c) predict local average signal strength, (d) characterize statistical median path loss, and (e) predict coverage areas and service availability.

2. Medium-scale, slow-varying path loss models having log-normal distributions include medium-scale components that capture variations in the signal power over distances much larger than a few wavelengths. The idea is that the signal power measured at two different locations may be different from each other for the same Tx to Rx separation. It is commonly represented in terms of the mean signal strength and its variation around the mean resulting from shadowing.
3. Small-scale propagation models characterize the fast-varying signal with randomly distributed amplitude with or without LOS connection. These models describe the fading effects from rapid fluctuations of the radio wave amplitude over a short period of time (a few milliseconds up to seconds) or over a short travel distance (a few wavelengths) (Rappaport 2002). The small-scale models consider the fading associated with the superposition of the multipath radio waves at the receiver. The fading effects in the channel could be severe when the transceivers or the surrounding environments are in motion. With mobility, the received signal power may fluctuate by as much as 40 dB by moving a fraction of the wavelength.

In this section, we present a summary of the large- and medium-scale propagation modeling of the channel. The main objective is to present several methods of predicting path loss of a radio link between the Tx and the Rx. In practice, the aim is to deliver sufficient signal power to the Rx so that the required performance objective is achieved.

Path Loss Modeling

Path loss (PL) is a term used to characterize the relationship between the transmitted power, P_t , and received power, P_r , in a radio link. There are several PL models depending on the environment and the assumptions made. For example, *simple analytical models* are used for understanding and predicting individual paths and specific obstruction cases. We also have *general area models* used mainly for early system dimensioning, primarily driven by statistics and measurements. Finally, there are *point-to-point models* that are essentially analytical models used for detailed area coverage and system planning. These models are summarized in Figure 5, and the general concepts of the most commonly used models are highlighted in this section.

Free Space Propagation Path Loss

Although a transmitted radio wave in free space encounters no obstructions, the energy of the wave spreads out as it propagates. This spreading out of energy results in

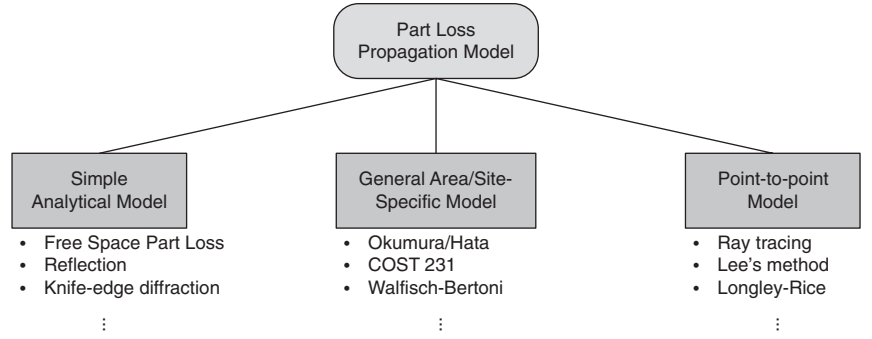

Figure 5: Propagation path loss modeling

the lowering of the intensity of the wave at some distance d from the source. This reduction in intensity is commonly referred to as *loss*. This is the loss that would be expected in an FS propagation environment or in a region free of any obstacles—the ideal case.

Calculating FS transmission loss is quite simple. Consider a Tx with power P_t coupled to an antenna that radiates energy equally in all directions (isotropic antenna). At a distance d from the Tx, the radiated power is distributed uniformly over a spherical area of $4\pi d^2$ (i.e., the surface area of a sphere of radius d). The channel attenuation, α , is defined as the ratio of the received power P_r and transmitted power P_t , which is given as

$$\alpha = \frac{P_r}{P_t} = G_t G_r \left(\frac{\lambda}{4\pi d} \right)^2 = G_t G_r \frac{1}{PL_{fs}}, \quad (2)$$

where PL_{fs} (in dB) is the FS path loss. This implies that the signal-loss factor after accounting for transmit and receive antenna gains is given by

$$PL_{fs}(d) = \left(\frac{4\pi d}{\lambda} \right)^2 = \left(\frac{4\pi d f}{c} \right)^2, \quad (3)$$

where f is the carrier frequency and c is the speed of light in FS. Notice that PL_{fs} is proportional to f^2 and d^2 , the classic square-law dependence of signal power level and distance. Any doubling of the range or frequency increases PL_{fs} by a factor of 4 and reduces the received power in Equation 1 by a factor of 4. Note that PL_{fs} is valid only in the far-field range of $d_f > 2D^2/\lambda$ (or, equivalently, $d_f \gg D$ and $d_f \gg \lambda$), where D is the maximum dimension of the antenna.

We can express PL_{fs} in dB as follows:

$$PL_{fs}(d)_{dB} = 10 \log_{10} \left(\frac{4\pi d}{\lambda} \right)^2 = 20 \log_{10} \left(\frac{4\pi d}{\lambda} \right) = \begin{cases} 32.45 + 20 \log_{10} d + 20 \log_{10} f, & (d \text{ in km}, f \text{ in MHz}) \\ 36.6 + 20 \log_{10} d + 20 \log_{10} f, & (d \text{ in miles}, f \text{ in MHz}) \end{cases} \quad (4)$$

Hence, for a given frequency and distance, it is easy to compute precisely the PL_{fs} . The relationship between path loss and distance as well as frequency is clearly shown in

Equation 4. Each time the distance doubles, another 6 dB of signal is lost under FS conditions.

One may wonder as to why FS path loss is proportional to d^2 because, after all, the propagation is taking place in a vacuum (i.e., free space). But recall that the so-called loss is not a loss in the real sense because the wave is not dissipating energy, but simply spreading out. Because P_r is the product of incident power flux density and effective area (see Equation 1), it is also inversely proportional to d^2 , which results in a decrease in intensity as the wave propagates. This is the reason why PL_{fs} is often referred to as *spreading loss*.

Another point that troubles some people when they see equations 3 or 4 is that path loss also increases as the square of the frequency. Does this mean that the transmission medium is inherently lossier at higher frequencies? Because antennae are more directive at high frequency, the losses instead should be decreasing as the frequency increases.

To explain this, notice that, although absorption of RF energy by various materials (buildings, trees, water vapor, etc.) tends to increase with frequency, it does not apply to free space propagation. The frequency dependence in this case results solely from the decrease in the effective gain of the receiving antenna as the frequency increases. This is reasonable because the electrical physical size of a given antenna type is inversely proportional to wavelength. If we double the frequency, the linear electrical dimensions of the antenna increase by a factor of 2 and the capture area by a factor of 4. The antenna therefore captures four times the power flux density at the higher frequency versus the lower one, and it delivers 6 dB more signal to the receiver. However, in most cases, we lose part of this 6 dB back by a decrease in the antenna's efficiency and hence the gain of the receiving antenna.

Path Loss over Smooth Plane

FS propagation is seldom the only mechanism of propagation in wireless channels. Under normal propagation conditions, LOS path may have adequate Fresnel zone clearance and still have path loss significantly different from PL_{fs} . If this is the case, the cause is probably multipath propagation resulting from reflections. This mode of propagation is used to account for multiple reflections of radio waves over a smooth plane, which depends not only on the Tx–Rx distance and wavelength but also on the heights of the Tx and Rx antennae.

Figure 6: Two-ray propagation model

One common source of reflections is the ground, which is considered as a smooth surface. Ground reflection can be a major determinant of path loss and tends to be more of a factor on paths in rural areas compared to urban areas, because the ground reflection path in urban areas will often be blocked by the clutter of buildings and other infrastructure.

To illustrate this concept, a two-ray model is often used to demonstrate the effect of multipath propagation on the average received power. It assumes that the transmitted radio wave reaches the stationary Rx through a direct LOS path and indirectly by perfect reflection from the ground. This scenario is illustrated in Figure 6. The radio wave at the Rx is the sum of the FS propagation and a single reflected wave from the ground. The two rays arriving at the Rx can have different phases and, in the worst case, they can cancel each other out.

Assume for simplicity that the transmit and receive antennae are both isotropic radiators separated by distance d . The direct ray travels a distance d_1 , and the reflected ray travels a total distance of d_2 to reach the receiving antenna after reflecting from point A. The angle of incidence θ and angle of reflection are the same. The path loss in this case depends on the relative amplitude and phase relationship of the two signals. In cases where the ground-reflected path has Fresnel clearance and suffers little loss, the reflected amplitude may approach that of the direct path. Thus, depending on the relative phase shift of the two paths, we may have an enhancement of as much as 6 dB over the direct path alone or cancellation resulting in additional path loss of 20 dB or more. The amplitude and phase of the reflected wave depend on several variables—including conductivity and permittivity of the reflecting surface (reflection coefficient), frequency of the wave, angle of incidence, and polarization—that are beyond the scope of this chapter. More detailed analysis can be found in Rappaport (2002) and Mark and Zhuang (2003).

Taking into account the phase difference, the received signal power is given by Mark and Zhuang (2003):

$$P_r(d) = P_t G_t G_r \left(\frac{\lambda}{4\pi d} \right)^2 \left[1 + \alpha_f e^{-j\beta_f} e^{j(\theta_2 - \theta_1)} \right]^2, \quad (5)$$

where α_f and β_f are the amplitude attenuation and carrier phase shift of the reflection wave, respectively. If $\alpha \cong 1$ (i.e., reflection loss is negligible), and $\beta_f = \pi$, for $\theta \ll 1$, then Equation 5 can be simplified to

$$P_r(d) = 4P_t G_t G_r \left(\frac{\lambda}{4\pi d} \right)^2 \left[\sin^2 \left(\frac{2\pi h_r h_t}{\lambda d} \right) \right] \quad (6)$$

Hence, the corresponding path loss is (Mark and Zhuang 2003)

$$PL_{2\text{-ray}}(d) = -10 \log_{10} \left\{ 4 \left(\frac{\lambda}{4\pi d} \right)^2 \left[\sin^2 \left(\frac{2\pi h_r h_t}{\lambda d} \right) \right] \right\} \text{ dB}, \quad (7)$$

after accounting for the transmitting and receiving antennae gains.

The result in Equation 7 is consistent with previous results that, in general, the path loss increases with the distance d . Also, a plot of Equation 7 (see Mark and Zhuang 2003, Figure 2.17) will show that the path loss has alternate minima and maxima as the distance between the Tx and the Rx increases.

Log-Distance Path Loss with Shadowing

Free space and the two-ray path loss models predict the received power as a deterministic function of distance, frequency, and antenna heights. Both models represent the mean received power at distance d . In practice, however, the received power at some distance d is a random variable resulting from variation of the environment. The average received power varies from location to location in a random manner (Bertoni 2000). More precisely, the logarithmic value of the received signal power at distance d is normally distributed with standard deviation σ_{dB} around the logarithm of the local mean power. The magnitude of the standard deviation indicates the severity of signal fluctuations caused by irregularities in the receiving and transmitting antennae surroundings. The log-distance model generalizes path loss to account for environmental factors. The log-normal model allows for random power variations around the area mean power.

This model consists of two parts. The first part, given by

$$\bar{P}_r(d) = P_r(d_0) \left(\frac{d}{d_0} \right)^n, \quad d \geq d_0, \quad (8)$$

predicts the path loss as the average received power, $\bar{P}_r(d)$, at distance d , where d_0 is a close-in reference distance, $P_r(d_0)$ is the reference received signal at distance d_0 , and n is known as the path loss exponent, which is dependent on the environment. In this case, the path loss measured in dB is given by

$$\overline{PL}(d)_{dB} = \overline{PL}(d_0) + 10n \log_{10} \left(\frac{d}{d_0} \right). \quad (9)$$

The fact that the environment in the same Tx–Rx separation may be vastly different at two different locations is not considered by Equation 9. But path loss at a particular location is random and log-normally distributed about the mean.

The second part, denoted as X_σ , accounts for the shadowing effect, which reflects the variation of the received power at certain distances. X_σ is a zero-mean Gaussian-distributed random variable (in dB) with standard

Table 1: Typical Values of Path Loss Exponent n and Shadowing Deviation σ_{dB}

	Environment	Path loss exponent n	σ_{dB} (dB)
Outdoor	Free space	2.0	4.0–12
	Urban cellular/PCS	2.7–3.5	4.0–12
	Shadowed urban cellular/PCS	3.0–5.0	4.0–12
Indoor	Propagation LOS	1.6–1.8	3.0–6.0
	Office, soft partition	4.0–6.0	9.6
	Office, hard partition	4.0–6.0	7.0
	Factory, LOS	1.6–2.0	3.0–5.8
	Factory, obstructed	2.0–3.0	6.8

**Figure 7:** Diffraction loss calculations

deviation σ (also in dB). The standard deviation is larger than zero; in case of severe signal fluctuation, measurements indicate that it can be as high as 12 dB (Rappaport 2002).

Hence, the overall model of log-distance *path loss with shadowing* (PLWS) is represented by

$$\overline{PL}_{plws}(d)_{dB} = \overline{PL}(d_0) + 10n \log_{10} \left(\frac{d}{d_0} \right) + X_{\sigma}. \quad (10)$$

When the standard deviation, σ_{dB} , is zero, the log-normal model reduces to the conventional log-normal path loss model without shadowing, which could be seen as a specific case of the more general log-normal model. Some typical values of n and σ_{dB} are shown in Table 1. Larger values of n or σ_{dB} correspond to more obstructions or deviation from the mean value, respectively, and hence faster reduction in the average received power or variations.

Diffraction Path Loss

Diffraction loss is the loss of radio energy from obstructions (or shadowing) along the path of propagation that arise when the direct LOS is obstructed by objects larger than the λ . To calculate the loss introduced by these obstacles, obstructions that diffract signals are treated like sharply defined objects known as *knife edges* (Rappaport 2002). Loss is dependent on the number and geometry (especially the height) of the obstructions. Depending on the number of obstacles, the loss could be calculated assuming a single knife edge or multiple knife edges. It also measures the height of obstruction in relation to the height of antennae.

Figure 7 summarizes the geometry for the computation of path loss assuming single knife-edge obstruction.

A single obstruction with different heights represented by a triangle, a rectangle, and a pentagon are located at point A. Several cases are possible. The transmitter height (h_t) and receiver height (h_r) could be the same ($h_t = h_r$) or, more naturally, $h_t > h_r$. The obstruction heights denoted as h_1 , h_2 , and h_3 are compared with h_t and h_r as well as with λ . The same obstruction height may produce lower diffraction loss at higher λ than at lower λ . Radio waves grazing the top of the obstructions are shown as dotted lines. The angles of incidents and reflections are shown as α , β , and γ .

As in the two-ray propagation model, the path and the phase difference of the direct path and the diffracted wave can be estimated from the geometry of the environment with the obstruction taken into consideration. It can be shown that the phase difference can be approximated as

$$\Delta\theta = \frac{2\pi\Delta d}{\lambda} \cong \frac{2\pi}{\lambda} \times \frac{(d_a + d_b)h^2}{2d_a d_b}, \quad (11)$$

with the parameters of Equation 11 shown in Figure 7, where h is the height from the LOS ray to the height of the obstruction.

To quantify diffraction losses, $\Delta\theta$ is normalized by the Fresnel-Kirchhoff diffraction parameter v , such that $\Delta\theta = \pi v^2/2$, where v is a dimensionless parameter given by

$$v = h \sqrt{\frac{2}{\lambda} \left(\frac{1}{d_a} + \frac{1}{d_b} \right)} = h \sqrt{\frac{2(d_a + d_b)}{\lambda d_a d_b}} \quad (12)$$

By convention, v is positive when the direct path is blocked (i.e., the obstacle has positive height, $h > 0$) and negative when the direct path has some clearance (i.e., the obstacle

has negative height, $h < 0$). When the direct path just grazes the object, then $h = v = 0$. Therefore, the knife-edge diffraction gain or loss in dB is then given as a function v according to the following equation (Rappaport 2002):

$$G_d(\text{dB}) = \begin{cases} 0 & v \leq -1 \\ 20\log(0.5 - 0.62v), & -1 \leq v \leq 0 \\ 20\log(0.5\exp(-0.95v)), & 0 \leq v \leq 1 \\ 20\log\left(0.4 - \sqrt{0.1184 - (0.38 - 0.1v)^2}\right), & 1 \leq v \leq 2.4 \\ 20\log(0.225v), & v > 2.4 \end{cases} \quad (13)$$

For multiple obstructions between the Tx and the Rx, approximate techniques for computing diffraction loss have been proposed in Bullington (1977), Epstein and Peterson (1953), and Deygout (1966, 1991). In Bullington (1977), multiple obstructions are replaced by a single equivalent obstruction at the point where the LOS from the Tx and Rx intersect. This results in oversimplification of the model. In Epstein and Peterson (1953), loss of individual obstructions is calculated by drawing LOS between each obstacle. Then the diffraction loss of each obstacle is added to obtain the overall loss. This gives poor results when the obstructions are especially close to each other. In Deygout (1966, 1991), a search for the “main” obstacle location—that is, the point where the highest value of v occurs along the path—is first determined and used to compute the loss. Then diffraction losses over “secondary” obstacles are added to the diffraction loss over the main obstacle. The approach can achieve reasonably good agreement with more rigorous approaches, but in general it overestimates the diffraction loss in increasingly greater amounts as the path length increases.

EMPIRICAL PATH LOSS MODELS

Most mobile communication systems operate in complex propagation environments that cannot be accurately modeled by the large-scale path loss models described above. Several models based on measurements have been used to predict path loss in typical operating environments. These models are mainly based on measurements in a given frequency range and geographical area and then developed into analytical approximations of propagation losses. However, application of the models is not restricted to the frequencies or geographical areas on which they were developed. In practice, many cellular system designs use these models as a basis for performance analysis, to estimate link budgets, cell sizes and shapes, capacity, and handoff criteria. In this section, the most common types of empirical models are summarized.

Okumura Model

One of the most common models for signal prediction in urban areas is the *Okumura model* (Okumura, Ohmori, and Fukuda 1968). The model is based on detailed analysis of measurements made in Tokyo and its suburbs in late 1960s and early 1970s. The collected data included measurements on terrestrial wireless microwave channel,

which takes into account some of the propagation parameters and terrain information. With the measured data, Okumura produced analytical expression and a set of curves giving the median attenuation relative to free space in an urban area as a function of effective Tx and Rx antenna height. Different curves were produced for different coverage areas such as open, quasi open, suburban, and urban areas. The measurement were conducted with effective Tx antenna height $h_t = 200$ m and effective Rx antenna height $h_r = 3$ m, $1 \leq d \leq 100$ km, and $150 \leq f \leq 1920$ MHz.

The analytical structure of the Okumura model is given by

$$L_p(d) = PL_{fs} + A_{mu}(f, d) - G(h_t) - G(h_r) - G_{area}, \quad (14)$$

where $L_p(d)$ is the median value of the propagation path loss, $A_{mu}(\cdot)$ is the median attenuation relative to FS, $G(h_t)$ is the base station height gain factor, $G(h_r)$ is the mobile station height gain factor, and G_{area} is the gain resulting from the environment. The antenna height gains are strictly a function of height, and the model is valid for Rx antenna heights ranging from 30 m to 1000 m.

To determine path loss using Okumura's model, PL_{fs} is first determined, and then the correction values $A_{mu}(\cdot)$, $G(\cdot)$, and G_{area} are obtained from either the plots or equation and then added to the PL_{fs} according to Equation 14.

Okumura's model typically results in 10 dB to 14 dB standard deviations between path loss predicated by the model and actual measurements in urban and suburban cellular systems. This model has served as the basis for high-level design of many existing wireless systems and has spawned several newer models adapted from its basic concepts and numerical parameters.

Hata Model

The *Hata model* is another commonly used empirical PL model (Hata 1980). This model is the empirical formula derived from Okumura's path loss measurements. The objective is to facilitate automatic calculation without the need for plots. The Hata PL equations are given as follows:

$$\begin{aligned} L_p(\text{urban}) &= 69.55 + 26.16 \log f - 13.82 \log h_t \\ &\quad + (44.9 - 6.55 \log h_t) \log d - a(h_r) \\ L_p(\text{suburban}) &= L_p(\text{urban}) - 2(\log(f/28))^2 - 5.4 \\ L_p(\text{rural}) &= L_p(\text{urban}) - 4.78(\log f)^2 - 18.33 \log f - 40.98, \end{aligned} \quad (15)$$

where the parameters in this model are the same as the Okumura model. The Rx antenna gain correction factors are given by

$$a(h_r) = \begin{cases} (1.1 \log f - 0.7)h_r - (1.56 \log f - 0.8), & \text{suburban, rural} \\ 8.29(\log 1.54h_r)^2 - 1.1, & \text{urban } f \leq 300 \text{ MHz} \\ 3.2(\log 11.75h_r)^2 - 4.97, & \text{urban } f > 300 \text{ MHz}. \end{cases} \quad (16)$$

This model is most suitable for use when $150 \leq f \leq 1500$ MHz, $30 \leq h_t \leq 200$ m, $1 \leq h_r \leq 10$ m, and $1 \leq d \leq 20$ km. Although the Hata model does not imply path-specific corrections, which are available in Okumura model, it has significant practical value and provides predictions comparable to the Okumura model, especially when $d > 1$ km. At distances less than 30 km, Hata values compare favorably within ± 1 dB of the Okumura values. At distances beyond 30 km, the Okumura curves drop below the Hata values. At 100 km, the difference varies from 7 dB to 15 dB.

This model is well suited for outdoor macrocell but not for personal communication systems, which have cells on the order of 1 km radius or less. Thus, it is a good model for first-generation cellular systems but does not model propagation well in current cellular systems with smaller cell sizes.

The COST-231 Model

The COST-231 model developed by the European Cooperative for Scientific and Technical (COST) research committee is one extension of the Hata model (COST 1991). It extends the model to the 1.8–2.0 GHz band in anticipation for use in the 1900 MHz PCS band. The COST path loss model is given by:

$$L_p(\text{urban}) = 46.3 + 33.9 \log f - 13.82 \log h_t - a(h_r) + (44.9 - 6.55 \log h_t) \log d + C_M, \quad (17)$$

where the city size correction factor $C_M = 0$ for medium city and suburban area and $C_M = 3$ dB for metropolitan centers. The COST-231 model parameters have the following ranges: $1500 \leq f \leq 2000$ MHz; $30 \leq h_t \leq 200$ m; $1 \leq h_r \leq 10$ m; and $1 \leq d \leq 20$ km.

Walfisch-Bertoni Model

One of the drawbacks of the Okumura-type models discussed previously is that they do not consider the impact of diffraction from surrounding buildings. As cellular mobile radio systems migrated from 800 MHz (or 900 MHz) to 1800 MHz (or 1900 MHz), the effect of propagation became more pronounced at 1800 (or 1900 MHz) compared to 800 (or 900 MHz). Reflections are more effective, shadowings from obstructions are deeper, foliage absorption is more attenuative, and penetration into buildings through openings became more effective, but material absorption within buildings and their walls is more severe. Consequently, the net result is the greater signal loss for systems in the 1800 MHz (or 1900 MHz) range compared to the 800 MHz (or 900 MHz) range. Overall, coverage radius of a 1800 MHz (or 1900 MHz) base station compared to 800 MHz (or 900 MHz) is approximately two-thirds the distance, which would be obtained with the same effective radiation power and same antenna height. In this type of environment, the Okumura-type models will not work well.

For these reasons, Walfisch and Bertoni (1988) developed a model aimed at improving the accuracy by exploiting the actual propagation mechanisms involved. This

model considers the effect of rooftop diffraction and ray “channeling,” which is significant in big metropolitan area. The Walfisch-Bertoni (WB) part loss model is given by

$$PL_{WB} = PL_{fs} + PL_{FT} + PL_{MS}, \quad (18)$$

where PL_{fs} is given in Equation 3, PL_{FT} is the rooftop-to-street diffraction and scatter loss, and PL_{MS} is the multi-screen diffraction loss. This model has been considered for use by the Radiocommunication sector of the International Telecommunication Union (ITU-R) in the International Mobile Telecommunications 2000 (IMT 2000) standards activities (Sarkar et al. 2003).

Wideband PCS Microcell Model

Another model of interest is the *wideband PCS model* (Feuerstein et al. 1994). It is essentially a two-ray ground reflection model for a LOS microcell environment. The measurement was conducted for a cellular system in California's San Francisco Bay Area using 20 MHz pulsed Tx at 1900 MHz with $h_t = 3.7$ m, 8.5 m, and 13.3 m; and h_r of 1.7 m. If d_f represents the distance at which the first Fresnel zone just becomes obstructed by the ground, and assuming flat ground reflection, the average path loss given by this model is

$$\overline{PL}(d) = \begin{cases} 10n_1 \log(d) + \overline{PL}(d_0) & \text{for } 1 < d < d_f \\ 10n_2 \log(d/d_f) + 10n_1 \log(d_f) + \overline{PL}(d_0) & \text{for } d > d_f, \end{cases} \quad (19)$$

where n_1 and n_2 are the path loss exponents, which are functions of the environment, and

$$d_f = (1/\lambda) \sqrt{16h_{te}^2 h_{re}^2 - \lambda^2(h_{te}^2 + h_{re}^2) + (\lambda^4/16)}. \quad (20)$$

This model is a double regression model, assuming regression breakpoint at the first Fresnel zone clearance. The model fits measured data well and agrees with the log-distance path loss model for dense urban microcell environments.

Longley-Rice Model

The Longley-Rice model (Longley and Rice 1968) is used for point-point communication systems under different types of terrain and over the frequency ranges from 40 MHz to 100 GHz. It is usually referred to as the *irregular terrain model* in which the median transmission loss is predicted using the path geometry of the terrain profile and the refractivity of the troposphere. Urban factors account for additional attenuation because of urban clutter near the receiving antenna. The signal strength of the radio wave in different environments is predicted using different techniques such as two-ray ground reflection and knife-edge techniques. This model is essentially a computer program with general input to the program including frequency, distance, antenna heights, polarization, surface

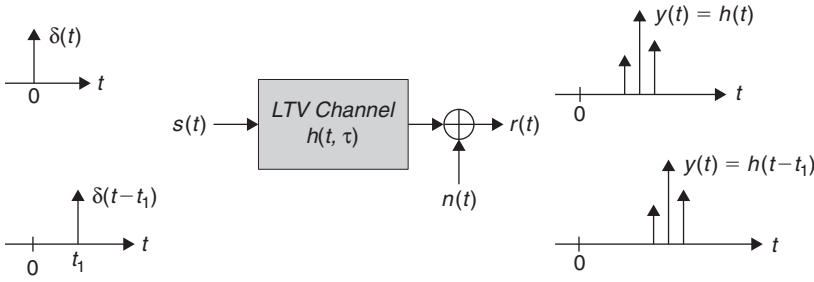

Figure 8: A wireless channel model as a linear system with impulse response $h(t, \tau)$ and noise $n(t)$

refractivity, Earth radius, climate conditions, and ground conductivity. Other specific parameters include antennae horizon and elevation angle, transhorizon distance, and terrain irregularity. This model does not consider the effects of buildings, foliage, and multipath propagation.

Durkins Model

The Durkin model (Durkin 1977) is similar to the Longly-Rice model. It is a computer simulator for predicting field strength contours over irregular terrain. It consists of two parts: the ground profile and the expected path loss. The *ground profile* is reconstructed from the topographic data of the proposed surface along the radial distance joining transmitter and receiver. It is used to model LOS and diffraction derived from obstacles and local scatters and assumes that all the signals are received along the radial (no multipath). The second part calculates the expected path loss along the radial by moving the receiver location in order to deduce signal strength contour. This model seems to have a pessimistic prediction in narrow valleys and tries to identify weak reception areas. The major disadvantage of this model is that it cannot adequately predict propagation effects because of foliage and buildings and cannot account for multipath propagation.

STATISTICAL WIRELESS CHANNEL MODEL

In the previous section, we examined the characteristics of the signal strength through the wireless channel based on large-scale signal propagation or fading. The average strength of the received signal is determined as a function of the Tx–Rx distance and frequency. However, because of multipath propagation and the complex interactions of the radio wave with the environment, the received signal consists of many radio waves with randomly distributed amplitudes, phases, and angles. Although the large-scale characteristics of the channel are necessary for proper link budget design, the small-scale statistical characteristics are vital in proper Rx design.

In this section, we examine the small-scale propagation effects of the wireless channel commonly known as *multipath fading*. This involves the rapid and often dramatic fluctuation of signal amplitude and phase resulting from the multipath phenomena. Unlike large- and medium-scale propagation, multipath fading is a result of the rapid fluctuation in the multipath signal amplitude over a short period of time or over short distances. Our discussion of

small-scale multipath fading will be a summary because of space limitations.

Channel Impulse Response

Multipath fading of the wireless channel is commonly described by the impulse response, which introduces a filtering action on the signal. Figure 8 represents a *linear time variant* (LTV) channel, where $h(t, \tau)$ is the time-variant impulse response. An impulse at the transmitter will result to multiple impulses at the receiver. The main goal is to statistically characterize the rapid fluctuations of the amplitudes, delays, and phases of the multipath signal. If the channel is bandlimited, then $h(t, \tau)$ can be described by the complex baseband equivalent representation. However, a more realistic representation is to model the multipath channel by taking different snapshots of complex baseband equivalent impulse responses at discrete time intervals. This implies that at time t , the channel can be modeled as a linear filter with time-varying impulse response given by

$$h(t, \tau) = \sum_{k=0}^{N(t)-1} \alpha_k(t, \tau) e^{-j2\pi f_c \tau_k(t) + \phi_k(t, \tau)} \delta(\tau - \tau_k(t)) \quad (21)$$

where $\alpha_k(t, \tau)$ and $\tau_k(t)$ are the amplitudes and excess delay of the k th multipath component, respectively; $\delta(\cdot)$ is the unit impulse function; and $2\pi f_c \tau_k(t) + \phi_k(t, \tau)$ represents all mechanisms of phase shifts of the k th multipath component; while $N(t)$ represents the number of multipath components, which generally can be a function of time. Most often, the phase shifts are represented as one variable—that is, $2\pi f_c \tau_k(t) + \phi_k(t, \tau) = \theta_k(t, \tau)$.

In a wireless channel, all of the parameters— $\alpha_k(t, \tau)$, $\tau_k(t)$, $\theta_k(t, \tau)$ and $N(t)$ —are unknown and, because they change over time, are often characterized as random processes. The amplitude attenuation $\alpha_k(t, \tau)$ may be obtained from the path loss and shadowing models described above, while $\theta_k(t, \tau)$ depends on delay and Doppler shift. It is commonly assumed that these two random processes are independent. If the multipath components have variable propagation delays that depend only on the receiver location and not on time, then the system can be modeled as a linear time-invariant filter.

Note that the phase $\theta_k(t, \tau)$ is most often assumed to be uniformly distributed over $[0, 2\pi]$, whereas the path gain model and distribution function depend on the nature of the channel and the propagation environment. The path

gain distribution is commonly assumed to be a Rayleigh-, Rician-, or Nakagami-distributed random variable, but details of these distributions are beyond the scope of this chapter.

Using Equation 21, the received signal given by

$$\begin{aligned} r(t) &= s(t) * h(t, \tau) + n(t) \\ &= \text{Re} \left\{ \sum_{k=0}^{N-1} \alpha_k(t) e^{-j\theta_k(t)} x(\tau - \tau_k(t)) e^{j2\pi f_c t + \phi_0} \right\} + n(t), \end{aligned} \quad (22)$$

is a superposition of all signal arriving at the Rx with various amplitudes, phases, and time delays, where $*$ is the convolution operator; $x(t)$ is a complex baseband equivalent signal (with bandwidth B , power P_t , carrier frequency f_c , and an arbitrary initial phase ϕ_0), and $s(t) = \text{Re}[x(t)e^{j(2\pi f_c t + \phi_0)}]$ is the transmitted signal. From Equation 22, one can conclude that the received signal is a series of time-delayed, phase-shifted, attenuated versions of the transmitted signal. At times, the complex-valued vectors $r(t)$ add destructively to reduce the power level of the receiver or add constructively to produce a large signal value.

One way to model a time-variant multipath channel is by using the *tapped delay line* model illustrated in Figure 9. The channel model consists of a tapped delay line with uniformly spaced taps. The tap spacing between adjacent taps is $T_c = 1/B$, the time resolution that can be achieved by transmitting a signal of bandwidth B . The tap coefficients denoted as $c_n(t)$, $n = 1, 2, \dots, N$, are usually modeled as complex-valued, uncorrelated Gaussian random processes. The length of the delay line corresponds to the amount of time dispersion in the multipath channel, which is usually called the *multipath spread* denoted as $T_m = N/B$, where N represents the maximum number of possible multipath signal components.

Channel Transfer Functions

Because time and frequency are inversely related, $h(\tau, t)$ can also be examined in the frequency domain via

Fourier transformation. In addition to impulse response $h(\tau, t)$, the channel can be characterized by the time-variant transfer function $H(f, t)$, the channel output Doppler-spread function $D(f, \nu)$, and the delay Doppler-spread function $S(\tau, \nu)$.

Time-variant transfer function is the Fourier transform of the impulse response with respect to the delay variable τ and is given by

$$H(f, t) = F_\tau[h(\tau, t)] = \int_{-\infty}^{\infty} h(\tau, t) e^{-j2\pi f \tau} d\tau \quad (23)$$

At any instant, $H(f, t)$ characterizes the channel in the frequency domain. If the channel changes with t , then $H(f, t)$ also changes with t . However, for a time-invariant channel, the impulse response is independent of the time variable t , and the transfer function varies only with the frequency variable f and is independent of t . Conversely, the inverse Fourier transform of the transfer function will give the impulse response. As a wireless channel can be characterized equivalently in frequency domain, a channel being time varying in the time domain means a channel is introducing Doppler shifts in the frequency domain. In fact, a wireless channel usually introduces continuous Doppler shifts, which results in the spectral broadening of the transmitted signal in the frequency domain.

The output Doppler-spread function $D(f, \nu)$, which is the channel gain associated with the Doppler shift ν at frequency f , is the Fourier transform of the time-variant transfer function $H(f, t)$ with respect to the time variable, t , and is defined as

$$D(f, \nu) = F_t[H(f, t)] = \int_{-\infty}^{\infty} H(f, t) e^{-j2\pi \nu t} dt \quad (24)$$

Hence, time variation of the impulse response is equivalent to the Doppler shift in the frequency domain.

Another function of interest is the delay Doppler-spread function $S(\tau, \nu)$, which is the Fourier-transform

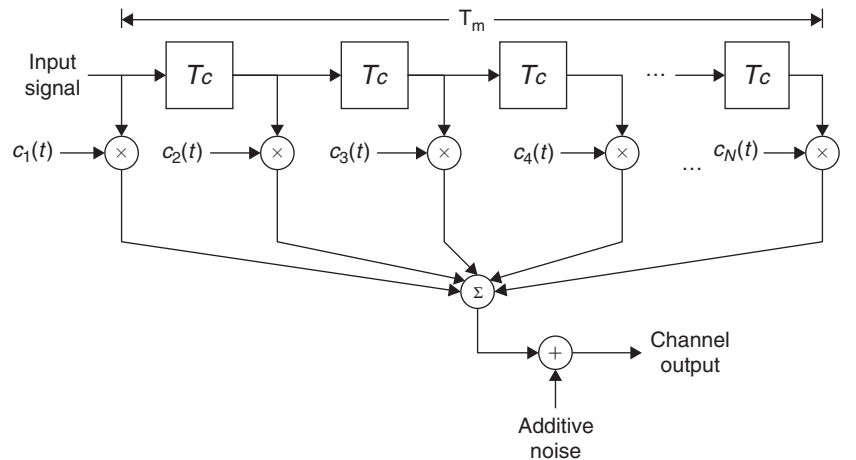

Figure 9: Equivalent model for a time-variant multipath channel

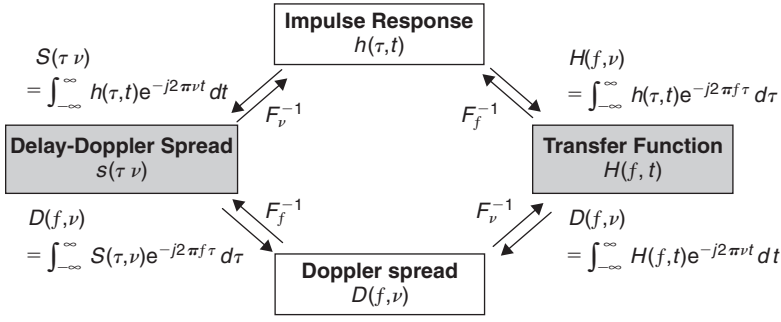

Figure 10: Relationship between the system functions

of the time-variant impulse response with respect to the time variable t , which is defined as

$$S(\tau, \nu) = F_t[h(\tau, t)] = \int_{-\infty}^{\infty} h(\tau, t) e^{-j2\pi\nu t} dt \quad (25)$$

Because the transmitted signal and the received signal can be represented in time or frequency domain, we can characterize the channel in time or frequency domain using the above four functions: $h(t, \tau)$, $H(f, t)$, $D(f, \nu)$, and $S(\tau, \nu)$. The relationship between these channel functions is shown in Figure 10. These functions enable us to characterize the channel in time and frequency domains, as well as in distance and velocity relationship.

Channel Scattering Functions

In practice, the channel may change with time in a random manner. This means that $h(t, \tau)$, $H(f, t)$, $D(f, \nu)$, and $S(\tau, \nu)$ are random processes and will require additional characterization. These functions are random processes with zero mean. In particular, $h(t, \tau)$ is a *wide sense stationary* (WSS) process and uncorrelated at τ_1 and τ_2 , for any t . Such a channel is said to be a *wide sense stationary uncorrelated scattering* (WSSUS) channel.

This channel model is an important class of practical channels in which it is assumed that the signal variations on the paths arriving at different delays are uncorrelated, such that the statistical properties of the channel do not change with time. Hence, the channel can be examined in terms of the correlation functions.

The correlation functions of a WSSUS channel are related to the above system functions and can be represented by four correlation functions denoted as

$$P_h(\tau, \Delta t), P_H(\Delta f, \Delta t), P_D(\Delta f, \nu), \text{ and } P_S(\tau, \nu) \quad (26)$$

where $P_h(\tau, \Delta t)$ is called the *space-time correlation function*, $P_H(\Delta f, \Delta t)$ is the *spaced-time, spaced-frequency correlation function*, $P_D(\Delta f, \nu)$ is the *spaced-frequency Doppler spread function*, and $P_S(\tau, \nu)$ is the *delay Doppler spread function*. Details of these functions can be found in Proakis (2000).

By allowing one of the variables in Equation 26 to be zero, the following one-dimensional functions can be obtained:

1. *power delay profile* (also known as the *multipath intensity profile*), $P_h(\tau)$;
2. *frequency correlation function*, $P_H(\Delta f)$;
3. the *time correlation function*, $P_H(\Delta t)$; and
4. the *Doppler power spectrum*, $P_S(\nu)$.

$P_h(\tau)$ portrays the time-domain behavior of the channel whereas $P_H(\Delta f)$ portrays the frequency-domain behavior of the channel. The relationship of these correlation functions and the associated fading parameters is illustrated in Figure 11. Through these correlation functions, important statistical characteristics of the channel can be determined.

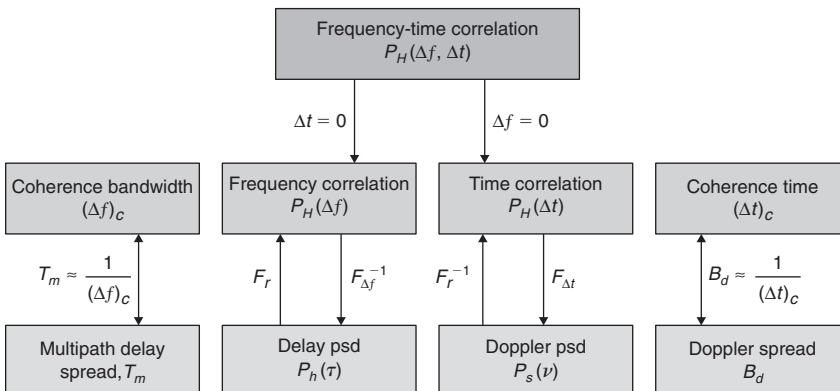

Figure 11: Relationship between system correlation functions

STATISTICAL PARAMETERS OF THE WIRELESS CHANNEL

From the impulse response, transfer functions, and correlation functions discussed above, several channel statistical parameters can be obtained. These parameters can provide insight into the effect of the channel on the transmitted signal. These statistical parameters include the power delay profile, time dispersion or delay spread, frequency domain correlation, Doppler spectrum (shift and spread), coherence bandwidth, and coherence time. As indicated above, these parameters and functions are random in nature and are characterized statistically. They directly affect receiver design and are useful for the proper descriptions of the channel in order to estimate the performance and methods of mitigating the effects of fading.

Power Delay Profile

The *power delay profile* $P_h(\tau)$, or *multipath intensity profile*, is the expected power (spatial average over a local area) per unit of time received with a certain excess delay. It is obtained by averaging a large set of impulse responses. It indicates the level of dispersion or distribution of transmitted power over various multipaths. From $P_h(\tau)$, we can compute the correlation of fading at different carrier frequencies and determine the multipath delay spread T_m , defined as the range of nonzero values of $P_h(\tau)$. T_m is an important parameter in characterizing wireless channels. The signal bandwidth B_s when compared to T_m will indicate the frequency selectivity and distortion level of the signal in the channel. Hence, from the power delay profile, we can compute the statistics describing the time-dispersion characteristics of the channel.

Time Dispersion

Recall that one of the most important differences between wireless and wired channels is that the wireless channel varies with time. Because of the mechanisms of propagation, time dispersion of the wireless channel varies widely from one location to another, and the resulting multipath channel response appears random as well. In multipath channel, each path has a different path length and different time of arrival at the receiver. This leads to the cumulative signal being smeared or spread in time, a phenomenon commonly known as *delay spread*. Because *time dispersion* depends on the geometrical relationships among the Tx, the Rx, and the surrounding physical objects, some parameters that can quantify the multipath channel are needed. Time dispersion can be characterized with channel parameters such as *excess delay*, *mean excess delay*, *root mean square (RMS) delay spread*, and *maximum excess delay*. These delays are determined in comparison to the first arrival path signal at the receiver with delay τ_0 . *Mean excess delay*, $\bar{\tau}$, or the *mean delay spread*, is the average delay measured in relation to the first arrival delay τ_0 . The *RMS delay spread* of the channel denoted as τ_{rms} is the square root of the second centralized moment of the power delay profile—that is, τ_{rms} is the standard deviation about the mean excess delay of the reflections weighted

proportional to their energies. The value of τ_{rms} describes the time delay spread in a multipath channel beyond what would be expected for free space LOS transmission. It characterizes the time dispersive nature or the multipath spread of the channel, which can be used to estimate the potential effect of conditions such as data rate of the signal and *intersymbol interference* (ISI). For reliable communication over a fading channel, it is required that the symbol period be greater than τ_{rms} (i.e., $T_s \gg \tau_{rms}$) in order to minimize the distortion in the channel. Because T_s is inversely proportional to the data rate, the inverse of τ_{rms} can be taken as a measure of the data-rate limitations of a fading multipath channel. Finally, the *maximum excess delay* is the maximum delay spread τ_m , which measures the time delay during which multipath power falls below a threshold, say, X dB. Numerical computation of these delays can be found in Proakis (2000).

Doppler Effect

In general, the output signal of a linear system does not have frequency components different from those of the input signal. However, both nonlinear and time-varying systems introduce new frequency components other than those existing in the input signal. In a wireless propagation environment, because of the mobility of users, surrounding scatterers, or both, the channel is linear but time variant. As a result, a wireless channel introduces frequency shifts to the transmitted signal, a Doppler-effect phenomenon. Because of the relative motion of Tx and Rx in mobile wireless channels, a Doppler frequency shift is impressed on the frequency of the transmitted signal. The Doppler shift, f_d , is given by $f_d = (v/\lambda)\cos(\theta)$, where v is the relative velocity between the Tx and Rx, λ is the wavelength of the transmitted signal, and θ is the angle of incident of received signal relative to direction of motion. This means that the received signal will be the frequency-shifted version of the transmitted signal. When the relative transceiver velocity varies with time, f_d will also vary with time.

Doppler spread, B_D (also known as the *maximum delay spread*), is the range of frequency over which Doppler power spectrum is nonzero. It represents the strength of the Doppler shift at different frequencies caused by movements of the terminals or objects close by. It is an indication of how the channel characteristics are changing with time, and it measures the spectral broadening caused by time rate of change of the channel.

Coherence Time and Bandwidth

From the multipath delay profile and the Doppler effect of the channel, the wireless channel is further characterized in time and frequency. The coherence time and coherence bandwidth are two additional parameters that are useful in characterizing fading and multipath effects in wireless channels. The coherence time, T_c , of the channel is used to characterize the time-varying nature of the frequency dispersiveness of the channel in time domain. It is a statistical measure of the time duration over which the channel impulse is invariant—that is, the time that

impulse response is stationary. This implies that two signals arriving with time separation greater than T_c are affected differently. Different symbols that are transmitted over the channel within the coherence time are affected by the same amount of fading. Different symbols that are transmitted over the channel outside the coherence time are most likely faded by different amounts. T_c is obtained by taking the reciprocal of the Doppler spread—that is, $T_c = 1/B_d$.

On the other hand, the coherence bandwidth, B_c , is a statistical measure of the bandwidth over which the channel characteristics of the signal (magnitude and phase) are highly correlated. Within this bandwidth, all frequency components of a signal will be affected similarly by the channel, and the channel is said to be “flat.” B_c is obtained as the reciprocal of the multipath spread and is defined as $B_c = 1/T_m$. Two signals separated in frequency greater than B_c will fade independently—that is, the statistical properties of the two signals are independent.

FADING IN WIRELESS CHANNELS

There are different types of fading. The type of fading experienced by a signal propagating through a wireless channel depends on the characteristics of the channel and nature of the transmitted signal. Depending on the parameters of the signal (e.g., wavelength, bandwidth, symbol period) and the channel parameters (e.g., RMS delay spread, Doppler spread), different transmitted signals will undergo different types of fading in the channel. Small-scale fading can be categorized based on two aspects: multipath delay spread (T_m) and Doppler spread (B_d). T_m leads to time dispersion and frequency selectivity of the channel. In this case, the channel may be classified as *flat fading* or *frequency selective fading*. T_m is a channel parameter in time domain, whereas the phenomenon in which the channel is flat or frequency selective corresponds to the frequency domain. Thus, the time-domain parameter, T_m , influences the channel characteristic in frequency domain.

On the other hand, Doppler spread (B_d) leads to frequency dispersion and time-selective fading. In this case, the channel may be classified as *fast-fading* or *slow-fading*. B_d is a channel parameter in frequency domain, whereas the phenomenon that the channel changes fast or slow is a time-domain effect. Therefore, the frequency domain parameter, B_d , influences the channel characteristic in time domain.

Knowing these relationships will help us design the system and determine the exact behavior of the signal in the channel. A summary of the fading effects in the wireless channel is illustrated in Figure 12.

If the coherence bandwidth, B_c , of the channel is much larger than the bandwidth of the transmitted signal, B_s , then the received signal undergoes flat fading. In that case, the symbol period is much longer than the multipath delay spread of the channel. In contrast, if B_c is smaller than B_s , the received signal suffers from frequency-selective fading. In this case, the symbol period T_s is smaller than T_m . When this happens, the received signal is distorted and ISI is induced. This means that it is much more difficult to model frequency-selective fading channels compared to flat fading channels, because each multipath has to be treated differently. Therefore, it is preferable to deal with a flat fading channel for signal transmission. Because we cannot change the multipath delay spread and coherence bandwidth of the channel, we can only try to design the symbol period T_s and signal bandwidth B_s such that flat fading of the channel results for the transmitted signal. Hence, to improve the performance of the transmission, given the delay spread, we choose a value for T_s that will result in a flat fading channel instead of a frequency-selective channel.

Based on the Doppler spread, the channel can be classified as *fast-fading* or *slow-fading*. If the channel impulse response (in time domain) changes quickly within T_s —that is, if the coherence time, T_c , of the channel is smaller than T_s —the received signal experiences fast fading. This will result in signal distortion. On the other hand, if the channel impulse response changes at a much

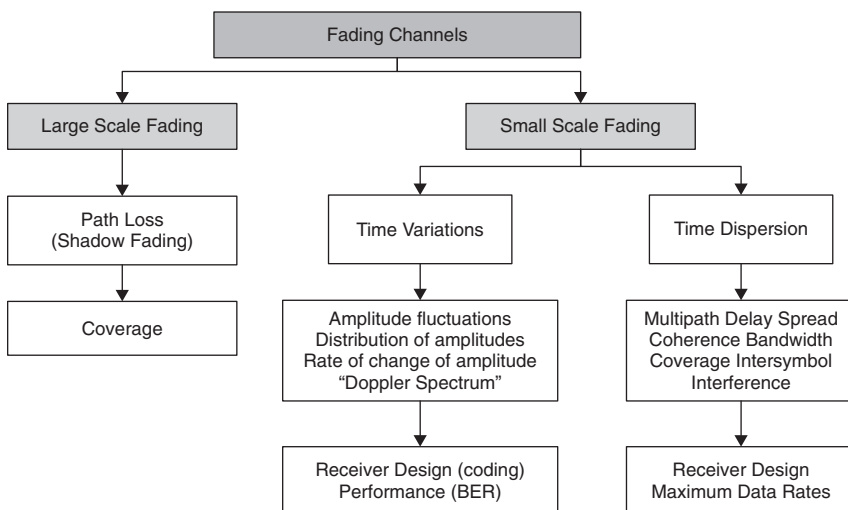

Figure 12: Summary of fading effects in wireless channel

Table 2: Classifications of Small-Scale Fading

Categorization basis	Fading types	Condition
Multipath delay spread	Flat	$B_s < B_c; T_s \geq 10\tau_{rms}$
	Frequency-selective	$B_s > B_c; T_s < 10\tau_{rms}$
Doppler spread	Fast	$T_s > T_c; B_s < B_d$
	Slow	$T_s < T_c; B_s > B_d$

slower rate than the transmitted baseband signal, then the received signal experiences slow fading. This means that the channel is stationary over certain symbol periods. It is easy to see that a slow-fading channel is preferable because it results in a more stable transmission quality.

Unfortunately, the Doppler spread is not determined by a system's design, although we can try to design T_s and B_s to achieve slow fading on the transmitted signal. In this case, given the Doppler spread, we choose B_s that will result in a slow-fading condition instead of a fast-fading one, resulting in better performance. The different types of fading and the conditions that give rise to them are summarized in Table 2.

CONCLUSION

The recent development in wireless communications has led to the emergence of new systems and services and yet the limitations of the wireless channel remain the same. These new systems and services strive to increase capacity and improve the QoS. For future generations of wireless systems that will require higher frequencies, smaller cell sizes, and more complex channel environments, there is a need for more accurate channel models and better site-specific propagation prediction models. New techniques such as smart antennae and multiple input and multiple output systems need new propagation prediction models to characterize the joint spatio-temporal channel. In this chapter, we have presented a review of the wireless channel characteristics in terms of large- and small-scale fading characteristics, as well as a review of the propagation prediction models that range from simple empirical formulas to modern site-specific models based on ray tracing. The channel characteristics in space domain are related to large-scale path loss. Small-scale fading presents the random fluctuations because of multipath propagation. This is a vast topic, and we have only scratched the surface in this chapter.

GLOSSARY

Attenuation: Weakening of radio frequency signals because they are partially blocked or absorbed. A process heavily dependent on the frequency of the radio wave and on the physical environment and material.

Autocorrelation: A measure of the similarity between a signal and a time-shifted replica of itself; a special case of cross-correlation.

Coherence bandwidth: One effect of multipath propagation is delay spread, which causes frequency-selective

fading. The coherence bandwidth is a measure of the delay spread whereby the larger the delay spread, the smaller the coherence bandwidth.

Coherence time: The time interval over which the received signal may be regarded as approximately constant.

Constructive interference: Interference that occurs when waves arriving at the receiver combine to form a single stronger wave. The strength of the composite wave depends on how closely in phase the two component waves are.

COST 231: The European Cooperation in Science and Technology program committee that deals with future mobile systems.

Delay spread: An effect of multipath for a digital interface in which multiple reflections of the same signal arrive at the receiver at different times, creating a noticeable degradation in signal quality.

Destructive interference: Interference that occurs when waves arriving at the receiver combine to form a single weaker wave. Usually occurs when waves that are out of phase combine to form a composite wave that is weaker than any of the component waves.

Doppler shift: The difference between the frequencies of the transmitted wave and of the echo received from a moving target.

Doppler spectrum: The power spectrum of the complex signal, expressed as a function of Doppler frequency or Doppler velocity.

Doppler spread: The width of the Doppler spectrum, measured in units of either frequency or velocity, which is usually defined as the standard deviation of the Doppler velocity about its mean value.

Fading: The random variation of the signal amplitude, phase, or both as a result of radio wave interactions with the transmission environment.

Free space loss: The power loss of a signal as a result of its spreading out as it travels through space. As a wave travels, it spreads out its power over space—that is, as the wave front spreads, so does its power.

IEEE 802.11: A WLAN standard (or set of standards) operating at 2.4 GHz and with data rates as high as 1 Mbps.

Industrial, scientific, and medical (ISM) band: A license-free band that is set aside for industrial, scientific, and medical equipment.

Isotropic radiator: A completely nondirectional antenna (one that radiates equally well in all directions). This antenna exists only as a mathematical concept and is used as a known reference to measure antenna gain.

Line of sight (LOS): Transmission in which the transmitting and receiving stations (antennae) can see each other—that is, a clear path between transmitting and receiving stations.

Multipath: A phenomenon whereby a radio signal reaching a receiving antenna arrives by multiple paths because of the various mechanisms of propagation. By traveling different distances to the receiver, the reflections arrive with different time delays and signal strengths. Signals that are in phase will add to one another. Signals that are out of phase will cancel one another.

Multipath fading: Fading that occurs when the direct path wave destructively interferes with its reflections at the receiver. The destructive interference is a result of the reflected waves arriving at the receiving end out of phase with the direct path transmitted wave.

Path loss: The average attenuation undergone by a radio wave as it propagates between the transmitter and a receiver. The loss may be the result of many effects, including free space loss, refraction, reflection, and absorption.

Personal communications service (PCS): Within the United States, an allocated 1.9-GHz band; the allocated spectrum is 120 MHz wide and is licensed as two 30-MHz segments for 51 major trading areas and three 10-MHz segments for 493 basic trading areas.

Radio frequency (RF): Also used generally to refer to the radio signal generated by the system transmitter or to the energy present from other sources that may be picked up by a wireless receiver.

Reflections: RF waves can reflect off of basically almost anything in the transmission environment. The reflections may vary in phase and strength from the original wave.

Root mean square (RMS): The square root of the average value of the square of the instantaneous signal amplitude; a measure of signal amplitude.

Scattering function: The average power density at the output of a fading channel as a function of the delay and Doppler shift.

Shadowing: Random fading resulting from blockage by objects in the signal path.

Voice over Internet protocol (VoIP): A technology that integrates voice and data transmission over the Internet.

Wide-sense stationary (WSS) process: A process whose mean and autocorrelation function are time-invariant.

Wide-sense stationary uncorrelated scattering (WSSUS): The statistical characterization of mobile radio channels with parameters of the channels (i.e., the appropriate system functions) assumed to be wide-sense stationary both *in time* and *in frequency*.

Wireless: Description of radio-based systems that allow transmission of telephone or data signals through the air without a physical connection such as a metal wire or fiber-optic cable.

Wireless local area network (WLAN): A flexible data communication system implemented as an extension to or as an alternative for a wired LAN. With WLANs, users can access shared information without looking for a place to plug in.

INTRODUCTION

Imperfections in the transmission media and disturbances in the surrounding environment are the main causes of errors. A significant portion of bandwidth can be lost because of errors. If data transmission was error free, then data communication would be a lot faster and cheaper. No transmission media is error free. Even fiber-optic cables, known for their reliability and used for extremely high-speed data communication links between continents, experience data corruption to some degree. Errors are caused by many factors, including type of transmission media, environmental effects, type of signal, and modulation scheme used. Error sources can be attributed to three major categories—namely, attenuation, distortion, and noise. However, there are techniques such as error detection and error correction that can be used to ensure data integrity. This is usually done by including redundant bits along with the data unit. Popular error-detection methods include parity check, cyclic redundancy checks, and so on. Hamming code is discussed as one example of an error-correction technique.

SOURCES OF ERRORS AND PREVENTION

Attenuation

Data are generally transmitted across communication networks in the form of electromagnetic waves (electrons or

photons according to the wave-particle duality principle). Similar to a car losing energy to friction as it moves, electromagnetic waves also tend to lose energy as they propagate through a medium. This loss of energy is referred to as *attenuation* (see Figure 1). The causes of attenuation include absorption and scattering of electrons or photons in the medium. Because work is done to overcome absorption and scattering, energy is released, usually as heat.

The attenuation level can be calculated by

$$P_{out} = P_{in} e^{-\alpha z}$$

where α is attenuation level and z is distance traveled by a wave in some medium.

For practical purposes, attenuation is generally expressed as the ratio of the output power to the input power, and generally expressed in decibels (dBs):

$$Attenuation(dB) = 10 \log_{10} \frac{P_{out}}{P_{in}} \text{ dB}$$

Attenuation is a physical property of the transmission media and cannot be eliminated. However, it is possible to mitigate its effects through the process of amplification. The components used to amplify signals are called *amplifiers* or *repeaters*. Amplification applied to a signal is often referred to as *signal regeneration*. It should be noted that attenuation and amplification are opposing processes.

Figure 1: Effect of attenuation on amplitude of signal

Figure 2: Distortion resulting from the different propagation constants and phases of the different Fourier components

In general, if

$$10\log_{10} \frac{P_{out}}{P_{in}} dB = \begin{cases} -ve & \Rightarrow \text{attenuation} \\ 0, & \Rightarrow \text{unity gain} \\ +ve & \Rightarrow \text{amplification} \end{cases}$$

Distortion

The propagation speed of an electromagnetic wave in a medium depends on its refractive index. In addition, data transmission is not limited to perfect sinusoids. Complex signals are often used. Jean Baptiste Joseph Fourier proved that any signal is composed of multiple harmonically related sinusoids, each of which has a different frequency and each of which can be considered as a different propagation mode with a different propagation constant. So each mode travels at a somewhat different speed; their net effect at the destination can be determined by using the superposition principle. The differential delay between the different sinusoids causes changes in the phase relationships, which leads to distortion of the signal. This is graphically illustrated by the amplitude versus time plots in Figure 2.

Distortion is sometimes referred to as *delay distortion* or *dispersion* (in fibers). Modal distortion can be reduced by compensating for the different propagation constants.

Noise

As mentioned earlier, another source of error in data transmission is noise. Unlike attenuation and distortion, it is often difficult to accurately quantize noise because of its random occurrence. Probabilistic methods are generally used to predict and counteract these effects. The common types of noise include white noise, impulse noise,

induced noise, cross talk, echo, and jitter. The effect of noise is quantized by the *signal-to-noise ratio* (SNR):

$$SNR = \frac{P_{signal}}{P_{noise}} \quad \text{or} \quad SNR(dB) = 10\log_{10} \left(\frac{P_{signal}}{P_{noise}} \right)$$

White Noise

White noise is also referred to as *thermal* or *Johnson noise* or *Nyquist noise*. White noise is caused by the random motion of electrons in the medium that generates a relatively constant random signal. The root mean square (rms) white noise voltage V_n can be expressed as:

$$V_n = \sqrt{4k_B T \Delta f R},$$

where k_B is Boltzmann's constant, T is temperature in degrees kelvin, Δf is bandwidth, and R is resistance of the circuit element. (See Figure 3.)

White noise can be eliminated by the use of filters. Removing white noise from a digital signal is often termed *signal regeneration*.

Impulse Noise

Impulse noise, also known as *burst noise*, is mostly caused by sudden changes in power. It is common because of many environmental factors that affect transmission media such as lightning and power surges. Analog signals affected by impulse noise are difficult to restore. As for digital signals, the higher the bit rate, the more consequent the impact of impulse noise. Impulse noise can be reduced in analog signals by the use of specialized filters. Digital signal processing on digital signals can reduce the effect of impulse noise (see Figure 4).

Figure 3: Effects of white noise; extreme noise can degrade the signal beyond recognition (amplitude versus time plots)

Figure 4: Digital signal affected by impulse noise

Figure 5: Cross talk between different transmission wires

Induced Noise

Any electromagnetic disturbance coming from the surrounding environment is classified as *induced noise*. Components such as motors and other electrical appliances are responsible for induced noise because they emit radio frequency waves and hence act as antennas. Transmission media often act as receivers, capturing these waves that lead to interference and subsequently corrupt the signal. This type of interference is commonly termed *radio frequency interference (RFI)*. Induced noise is not always constant but can be prevented by shielding.

Cross Talk

Cross talk is another type of induced noise caused by coupling between different wires. As mentioned in the previous section, some wires can act as antennas while others act as receivers. Cross talk is many times experienced with analog communication links—for example, when someone hears another phone conversation on top of the desired conversation on the same line. Cross talk is usually constant. As it is induced noise, it can be prevented with proper shielding. (See Figure 5.)

Echo

Echo is generated by the reflection of the original signal. This generally occurs wherever there is a discontinuity in the medium. Coaxial and fiber-optic cables are prone to noise because of echo. Severe echo can corrupt the original signal. Echo is usually constant and can be prevented through proper termination of the cables.

Collision

Collision occurs when two or more hosts attempt to send data packets simultaneously over the same transmission

line. (Details of collision will be discussed in a later chapter.) Data packets travel along the transmission line as electromagnetic waves. When two or more waves occupy the same medium simultaneously, they interfere and thus corrupt the original information. Collision is prevented by the medium access control sublayer (also discussed in detail in a later chapter).

Jitter

Small timing irregularities during digital signal transmission cause *jitter*. Jitter is accentuated by high transmission rate for digital signals, especially when the same signal is transmitted multiple times. The effects of jitter can be minimized by several techniques, including slower transmission rates, the use of fewer repeaters, and better-quality electronic components.

ERROR DETECTION

As previously discussed, data transmission is susceptible to corruption. The extent of corruption primarily depends on the transmission medium. For example, an optical fiber is more reliable than a twisted-pair. The types of data corruption (or errors) can be classified into two categories: single-bit error and burst error. A *single-bit error*, as the name implies, refers to errors where only one bit has altered—that is, a 1 has changed to a 0 or vice versa. Any other error, where more than one bit is altered, is called a *burst error*.

To detect errors, we need to know the original data. We could send each data unit more than once until the receiving party acknowledges it. However, this method would not be efficient. A bandwidth-efficient way to detect errors within a data unit is to append extra bits.

Figure 6: Circuit for calculating and checking parity

The receiving system can then check for consistency using the extra bits. Once the consistency is verified, the extra bits are discarded. These extra bits are termed as *redundant* or *check bits*. The data unit together with the redundant bits is usually called a *code word*. In the following sections, we will discuss how to generate the redundancy bits and how to detect errors using them.

Parity Check

Parity check is the most common, least expensive, and simplest error-detection algorithm. It is sometimes referred to as *vertical redundancy check*. This technique uses one bit as the redundant bit. There are two implementations of parity check—namely, even parity and odd parity. For *even parity*, the goal is to make the number of 1's in the code word even. Conversely, odd parity makes the number of 1's odd. For example, 101000 becomes 1010001 with odd parity and 101000 0 with even parity. The parity bit computation and check is implemented using an exclusive-or gate arrangement similar to that shown in Figure 6.

Parity check can detect all single-bit errors. It can also detect burst errors provided the total number of altered bits is odd. For example: 11001100 and 11001101 differ by one bit, which is detected by even parity check. The data units 10101010 and 01001010 differ by three bits, which is also detected by even parity check. However, if the number of bits altered is even, then parity check will fail. For example, 10010011 and 11100011 differ by two bits and yet have the same even parity. On the whole, despite being fast and cheap to implement, parity check is not especially reliable in detecting burst errors.

Longitudinal Redundancy Check

The *longitudinal redundancy check* (LRC) is an extension of parity checking. LRC uses parity checking to detect burst errors. The idea is to use multiple parity bits for one data unit. To implement LRC, the data unit is segmented into multiple portions; then the parity check for each of these portions is calculated and appended to the original data unit.

The data unit to be transmitted is segmented and arranged in rows and columns. The parity for each corresponding column is then calculated and appended to the original data unit. For example if we have a block of twenty-four bits, we can rearrange the data into four rows, each with six bits, and calculate the parity bit for each

column and append it to the original data unit, which then becomes $24 + 6 = 30$ bits long.

For example, we want to transmit 101010 011100 001101 110011. If we choose to break the message into four segments, we calculate the LRC with even parity as follows:

Segment 1	1	0	1	0	1	0
Segment 2	0	1	1	1	0	0
Segment 3	0	0	1	1	0	1
Segment 4	1	1	0	0	1	1
LRC	0	0	1	0	0	0

Therefore, the code word becomes 101010 011100 001101 110011 001000

Now suppose the data block 110001 101010 111011 101010 is corrupted to 110001 101001 001011 101010. The LRC bits will change from 001010 to 111001. Hence, this four-bit error is detected. Note how the total number of bits changed per column is odd. From this example, it is clear that LRC can detect multiple-bit errors or burst errors. However, if the total number of bits altered per column is even, then LRC will fail. For example, suppose the same data block gets corrupted to 110000 101011 111011 101010. Because the LRC bits remain unchanged, 001010, the LRC algorithm fails. We should expect this because we know that parity check fails when the total number of bits altered is even.

Block Sum Check

Block sum check is yet another implementation of parity check to detect burst errors. It is quite similar to LRC, but instead of only appending the parity for the columns, we also append the parity for the rows. The data unit is rearranged into a block, and the parity for both the rows and the columns is calculated. The resulting set of bits is referred to as the *block sum*. Figure 7 illustrates how block sum works.

As we observe, if the total number of errors in any column is even, then the error can be detected (LRC fails in such scenarios). Similarly, if the total number of errors in any row is even, then the error is detected. Block sum checking increases the probability of detecting burst errors as compared to LRC. However, if two bits are altered

	P ₀	A ₆	A ₅	A ₄	A ₃	A ₂	A ₁	A ₀
	1	0	0	0	0	0	0	0
	1	0	1	0	1	0	0	0
	0	1	0*	0	0	1*	1	0
	0	0	1	0	0	0	0	0
	1	0	1	0	1	1	0	1
	0	1	0*	0	0	0*	0	0
	1	1	1	0	0	0	1	1
	1	0	0	0	0	0	1	1
P ₁	1	1	0	0	0	0	1	1

Figure 7: Block sum example

in any two columns and rows simultaneously, then block sum fails. An example of such a failure is denoted by (*) in Figure 7.

Cyclic Redundancy Check

In the previous sections, we covered various implementations of parity check. We used longitudinal redundancy check and block sum check to compensate for the single-bit error-detection limitation of parity-checking algorithms. Despite these limitations, both methods were successful in detecting burst errors. However, the receiver end has to wait for the complete code word to arrive before performing any checks. Note also that the receiver end has no means of detecting which part of the data has corrupted; therefore, in case of any errors, the entire code word has to be sent again, which wastes bandwidth.

Cyclic redundancy check (CRC) is another error-detection scheme that compensates for all of the

limitations of the various parity check methods. It is based on polynomial codes and binary division. Calculations are performed in modulo 2 arithmetic. In essence, the CRC method divides the data unit by a divisor (called the *generator polynomial*) and uses the remainder bits as redundant bits. The receiver then divides the code word by the same divisor, and a remainder of zero verifies the integrity of the data. The number of redundant bits used must be one less than the number of bits in the divisor for the CRC to be valid.

The conversion of CRC binary data to polynomial codes proceeds as follows. Each bit is represented by a polynomial term with coefficient 0 or 1 (the value of that particular bit). Consider an n -bits long data unit, where each bit is represented by a term x^{n-1} , with coefficient either 0 or 1, depending on the value of that particular bit. The least significant bit has position 0, and the most significant bit has position n . For example, consider 11010: the polynomial equivalent is $1x^{5-1} + 1x^{4-1} + 0x^{3-1} + 1x^{2-1} + 0x^{1-1} = x^4 + x^3 + x$.

Let the generator polynomial be $G(x)$ of degree g and the transmitted data unit $D(x)$ of degree d and length m . The following steps describe the process of generating the CRC bits.

1. Append g zero bits to the low order of the data unit, which now becomes $m + g$ bits long. Let $D_{m+g}(x)$ represent the new polynomial.
2. Divide $D_{m+g}(x)$ by $G(x)$ using modulo 2 division.
3. Replace the g -appended zero bits by the remainder of the previous operation in the polynomial $D_{m+g}(x)$. The new polynomial, $T(x)$, represents the code word to be transmitted.

To detect errors using CRC, divide $T(x)$ by $G(x)$. If the remainder is not zero, then there is an error.

The following example illustrates CRC bit generation.

Let $D(x) = x^9 + x^7 + x^6 + x^4 + x^2 + 1$ and $G(x) = x^4 + x + 1$. Find the CRC bits and the frame to be transmitted.

The message is 1010010101; $G(x)$ is 10011. Because $G(x)$ is five bits long, we should append four zeros to the message before performing modulo 2 division. Therefore, the message becomes 1010010101 0000:

					1	0	1	0	1	0	1	0	1	0				
1	0	0	1	1	1	0	1	1	0	1	0	1	0	1	0	0	0	0
					1	0	0	1	1									
							1	0	1	1	0							
							1	0	0	1	1							
									1	0	1	1	0					
									1	0	0	1	1					
											1	0	1	1	0			

The remainder is 1110. Now we append this remainder to the original message to get the code word 1010010101 1110.

To check for errors on the receiver end, we perform modulo 2 division again:

					1	0	1	0	1	0	1	0	1	0				
1	0	0	1	1	1	0	1	1	0	1	0	1	0	1	1	1	1	0
					1	0	0	1	1									
							1	0	1	1	0							
							1	0	0	1	1							
									1	0	1	1	0					
									1	0	0	1	1					
											1	0	1	1	1			
											1	0	0	1	1			
													1	0	0	1	1	
														1	0	0	1	1
																		0

As we can see, the remainder is, in fact, confirming the integrity of the data. Now suppose our code word suffered from a burst error such as this: 11001101011110. We perform the CRC check:

					1	1	0	1	1	0	1	1	1	0				
1	0	0	1	1	1	1	0	0	1	1	0	1	0	1	1	1	1	0
					1	0	0	1	1									
						1	0	1	0	1								
						1	0	0	1	1								
								1	1	0	0	1						
								1	0	0	1	1						
									1	0	0	1	1					
										1	1	1	1	1				
											1	0	0	1	1			
												1	1	0	0	1		
													1	0	0	1	1	
														1	0	1	0	1
															1	0	0	1
																1	1	0
																		0

We can confirm that the remainder is not zero, so there is an error. A brief description of CRC operation is provided next for interested readers.

CRC Operation

Suppose we transmitted $T(x) = 10001010101$ and it was corrupted by $E(x) = 0001000100$, where the 1's represent positions where errors occurred. Then the received bit string would be $T(x) + E(x)$ (the + sign stands for exclusive-or or modulo 2 addition). The receiving party

would perform $\frac{T(x) + E(x)}{G(x)}$ or $\frac{T(x)}{G(x)} + \frac{E(x)}{G(x)}$. But because $\frac{T(x)}{G(x)} = 0$, the error depends on the result of $\frac{E(x)}{G(x)}$.

Case 1: Single-Bit Errors

$E(x) = xi$, where i is the error bit position. If $G(x)$ has more than one term, then $E(x)$ will never be divisible by $G(x)$, and hence the error will be detected.

Case 2: Double-Bit Errors

$E(x) = x^i + x^j$, where $i > j$ and both represent bit error positions. We rewrite $E(x)$ as $E(x) = x^j(x^{i-j} + 1)$. To be able to detect this type of error, first, $G(x)$ must not be divisible by x ; second, $G(x)$ must not divide $x^k + 1$, for any k up to $i - j$.

Case 3: Total Number of Erroneous Bits Is Odd

For an odd number of bit errors, the polynomial $E(x)$ will have an odd number of terms. To catch this type of error, $x + 1$ must be a factor of $G(x)$. It turns out that no polynomial with an odd number of terms has $x + 1$ as a factor in the modulo 2 system.

Case 4: Burst Errors

If the burst error is of length k , then $E(x) = x^i(x^{k-1} + \dots + 1)$. $G(x)$ will not have x^i as a factor if it has a term in x^0 . So, if the degree of $(x^{k-1} + \dots + 1)$ is less than that of $G(x)$, then the remainder will never be zero. If the degree of $(x^{k-1} + \dots + 1)$ is greater than or equal to the degree of $G(x)$, then the remainder will not necessarily be zero.

Summary of CRC Operation

In short, we should choose the generator polynomial such that it is not divisible by x but is divisible by $x + 1$. Such a generator polynomial with degree r will detect:

1. all single-bit errors,
2. all double-bit errors,
3. all odd-numbered bit errors (burst errors),
4. all burst error $\leq r$ in length, and
5. most burst errors $> r$ in length (if length $= r + 1$, probability of detection is $(2^{r-1} - 1)/2^{r-1}$ and if length $> r + 1$, probability of detection is $(2^r - 1)/2^r$).

An example of a CRC polynomial used in the IEEE 802 standard is $x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$. Based on the previous discussions, we can verify that this polynomial detects all bursts errors of length thirty-two or less and all burst errors with odd numbers of bits.

The hardware implementation of CRC is based on a shift register and exclusive-or gates as illustrated in Figure 8. Assume that $G(x) = x^4 + x + 1$. The bit string enters the circuit from the right.

Checksum

All of the error-checking methods discussed so far are mostly used by the lower-layer protocols. The upper-level protocols use the *checksum* method, which is based on the redundancy principle (like parity check, LRC, block sum check, and CRC). To calculate the redundancy bits, the sender party divides the data unit equally into two or more segments. These segments are then added together using one's complement. Any generated carry is added to

the sum to ensure that the sum has the same length as the segments. The complement of the sum is then appended to the original data unit as redundant bits. To detect errors, the receiver system determines the sum of the segments (the same length used by the sender) in the code word. If the complement of the sum is zero, then the data are error free.

Examples

Suppose we want to determine the code word for 1010111011100011 using checksum. First, we break the bit string into equal segments (let us divide it into two for simplicity). Then we calculate the checksum as follows:

Carry	1	1		1	1	1		
Segment 1	1	0	1	0	1	1	1	0
Segment 2	1	1	1	0	0	0	1	1
Sum	1	0	0	1	0	0	0	1
Add carry								1
New sum	1	0	0	1	0	0	1	0
Checksum	0	1	1	0	1	1	0	1

Therefore, the code word is 1010111011100011 01101101.

To verify the checksum, assume we use the above code word:

Carry	1	1		1	1	1	1	
Segment 1	1	0	1	0	1	1	1	0
Segment 2	1	1	1	0	0	0	1	1
Checksum	0	1	1	0	1	1	0	1
Sum	1	1	1	1	1	1	1	0
Carry								1
New sum	1	1	1	1	1	1	1	1
Complement	0	0	0	0	0	0	0	0

Because the result is zero, this is error free.

Assume the code word suffered a burst error and the new transformation is now 101000011100011 01101101:

Carry	1	1		1	1	1	1	
Segment 1	1	0	1	0	0	0	0	1
Segment 2	1	1	1	0	0	0	1	1
Checksum	0	1	1	0	1	1	0	1
Sum	1	1	1	1	0	0	0	1
Carry								1
New sum	1	1	1	1	0	0	1	0
Complement	0	0	0	0	1	1	0	1

Figure 8: CRC circuit

Because the new complement is not zero, it indicates a burst error.

Checksum detects all errors with odd numbers of bits, and most errors with even numbers of bits. However, there may be instances when an error with an even number of bits may go undetected. The following example illustrates such an instance:

Carry	1	1		1	1	1	1	
Segment 1	1	0	1	0	1	0	1	1
Segment 2	1	1	1	0	0	1	1	0
Checksum	0	1	1	0	1	1	0	1
Sum	1	1	1	1	1	1	1	0
Carry								1
New sum	1	1	1	1	1	1	1	1
Complement	0	0	0	0	0	0	0	0

Note how the complement is still zero despite the burst error. Such an error will go undetected. Table 1 synthesizes several references (Forouzan 2001; Halsall 1996; Tanenbaum 2002; Shay 1999) that summarize the different error-detection techniques and their advantages and limitations.

ERROR CORRECTION

Having seen how the detection of single-bit errors and burst errors works, we now need to devise methods to correct them. In the event of an error, there are only two possible alternatives: either correct it or request that the original data be retransmitted. When dealing with single-bit errors, data retransmission wastes significant amount of bandwidth. It is not worth retransmitting the whole data unit for just one erroneous bit, so if at all possible avoid retransmission. The receiver, then, needs some type of automatic error-correcting mechanism. For binary data, error correction is fairly easily accomplished. If a bit should not be 1, then it must be 0—and vice versa. Therefore, the error-correcting mechanism only needs to locate the error and complement its value. In practice, it is more efficient to only correct errors when the error is limited to one, two, or three bits because of the fact that the bigger the burst error, the more redundant bits are needed to accurately correct the errors. Therefore, in these scenarios, retransmission is more efficient.

Single-Bit Error Correction

As discussed earlier, the simplest way to detect single bit errors is parity check. The key to error correction is to locate the error; correcting it involves complementing the bit. So if we want to detect and correct the error, we must

Table 1: Summary of Error-Detecting Methods

Detection Method	Advantages	Limitations
Parity check (vertical redundancy check)	<ul style="list-style-type: none"> Simple and fast to implement Always detects single-bit errors Always detects odd-numbered bit errors 	<ul style="list-style-type: none"> Cannot detect errors when even number of bits are corrupted
Longitudinal redundancy check	<ul style="list-style-type: none"> Always detects single-bit errors Can detect most burst errors 	<ul style="list-style-type: none"> Fails when the number of bits altered per column is even within the block arrangement
Block sum check	<ul style="list-style-type: none"> Always detects single-bit errors Better than LRC in detecting burst errors 	<ul style="list-style-type: none"> Fails where an even number of bits are altered in any two columns and rows simultaneously within the block arrangement
Cyclic redundancy check	<ul style="list-style-type: none"> Most efficient and reliable Detects all single-bit errors Detects all double-bit errors Detects all odd-numbered errors Detects all burst errors $\leq r$ in length Detects most burst errors $> r$ in length (if length = $r + 1$, probability of detection is $(2^{r-1} - 1)/2^{r-1}$ or if length $> r + 1$, probability of detection is $(2^{r-1} - 1)/2^r$) 	<ul style="list-style-type: none"> Somewhat more complex to implement when compared to other parity check techniques
Checksum	<ul style="list-style-type: none"> Simpler to implement than CRC Always detects single-bit errors Always detects odd-numbered bit errors Detects most even-numbered bit errors 	<ul style="list-style-type: none"> Occasionally fails when an even number of bits are corrupted

Table 2: Hamming Code for a Seven-Bit-Long Data Unit

10	9	8	7	6	5	4	3	2	1	0
d_6	d_5	d_4	r_3	d_3	d_2	d_1	r_2	d_0	r_1	r_0

Table 3: Erroneous Bit Detection Using Hamming Code

$r_3 r_2 r_1 r_0$	Invalid parity checks	Erroneous bit position
0000	None	None
0001	d_0	0
0010	d_1	1
0011	d_0 and d_1	2
0100	d_2	3
0101	d_0 and d_2	4
0110	d_1 and d_2	5
0111	d_0 , d_1 , and d_2	6
1000	d_3	7
1001	d_0 and d_3	8
1010	d_1 and d_3	9
1011	d_0 , d_1 , and d_3	10

locate it. Hence, we need to include enough redundant bits so that we can locate the exact position of the error in the data unit. For a data unit m bits long, the redundant bits should be able to designate at least $m + 1$ states, pointing to no error; error in position 1 through error in position m . However, we also need to accommodate for errors in the redundancy bits themselves. Therefore, if we have r redundant bits, then the total number of states that need to be designated is $m + r + 1$. Because r bits can represent 2^r states, and we want to represent at least $m + r + 1$ states, we can solve for the ceil value of r from $2^r = m + r + 1$. Finally, using a code developed by R. W. Hamming—the *Hamming code*—we can detect the erroneous bits. The *Hamming distance* is defined as the number of different bits between the actual and received code word.

The Hamming Code

The Hamming code segments the data unit and calculates the even parity bits for each segment. The parity bits are then inserted at strategic positions in the transmitted data unit, as determined by $2^i + 1$, where i is the redundant bit number, assuming we start from position 0. To illustrate this concept, consider a data unit seven bits long: $d_6 d_5 d_4 d_3 d_2 d_1 d_0$. Using $2^r = m + r + 1$ with $m = 7$, the least integer value of the required redundancy bits (r) is 4. These redundant bits are called r_3 , r_2 , r_1 , and r_0 , and they are placed at strategic positions. The resulting Hamming code is shown in Table 2.

The even parity bits are calculated for the following data bits:

r_0 is calculated for positions 0, 2, 4, 6, 8, and 10.

r_1 is calculated for positions 1, 2, 5, 6, 9, and 10.

r_2 is calculated for positions 3, 4, 5, and 6.

r_3 is calculated for positions 7, 8, 9, and 10.

The Hamming code is tabulated in such a fashion that the combination of correct and erroneous parity reveals the location of the erroneous bit. It should be noted that r_0 is calculated using bits whose binary representations have a 1 in the zero position. Similarly, r_1 is calculated using bits with 1 in the first position and so forth. Table 3 illustrates this concept.

As an example, consider the message 1001011. The code word is

10	9	8	7	6	5	4	3	2	1	0
1	0	0	1	1	0	1	0	1	0	0

Assume that the code word transforms to 10011110100 because of a single bit error.

Checking each parity bit, we see that:

r_0 is 0, r_1 is 0, r_2 is 1, r_3 is 0

Therefore, the error is in location 0100. From Table 3, the location 0100 corresponds to d_2 ; and referring to Table 2, d_2 corresponds to location 5.

Burst-Error Correction

As previously discussed, the Hamming code is highly efficient at correcting single-bit errors. But we still have burst errors to deal with. To handle them, we can modify the Hamming code algorithm.

Table 4: Hamming Code Word Arrangement

d_6	d_5	d_4	r_3	d_3	d_2	d_1	R_2	d_0	r_1	r_0
d_6	d_5	d_4	r_3	d_3	d_2	d_1	R_2	d_0	r_1	r_0
d_6	d_5	d_4	r_3	d_3	d_2	d_1	R_2	d_0	r_1	r_0
d_6	d_5	d_4	r_3	d_3	d_2	d_1	R_2	d_0	r_1	r_0
d_6	d_5	d_4	r_3	d_3	d_2	d_1	R_2	d_0	r_1	r_0

The principle stays the same. The Hamming code words are arranged in a matrix before they are transmitted. The following two steps outline the process of encoding and transmitting the data.

1. Arrange the Hamming code words in a fashion so that they form a block or matrix (similar to the LRC arrangement).
2. Transmit the matrix one column at a time (instead of the conventional row method).

The receiver then reconstructs the original matrix one column at a time. Once the original matrix has been reconstructed, error correction is applied to each row. This technique ensures error correction even if the entire column is corrupted by a burst error. However, if multiple columns are corrupted in a fashion that leads to multiple erroneous bits in single row, then this technique will fail.

Suppose we want to transmit a data unit that is thirty-five bits long. First, we segment the data unit into segments: five in this case. Then we compute the Hamming code word for each segment: $d_6 d_5 d_4 r_3 d_3 d_2 d_1 d_0 r_1 r_0$. Finally the code words are arranged as shown in Table 4 and transmitted column-wise.

Table 5 summarizes the Hamming code and some other popular satellite and RF communication error-correction techniques. The details of most of these techniques are beyond the scope of this text. However, expected growth in wireless networking will make these techniques important, so the important features of the Hamming code and some other relevant techniques are tabulated in terms of their properties and applications by summarizing Hamming (1980), Peterson (1981), 4i2i Communications (2004a, 2004b, 2004c), Morelos-Zaragoza (1996), Wicker (1995), and Blleloch and Maggs (undated), for the interested reader in Table 5.

Table 5: Comparison of Various Error-Correcting Methods

Error-Correcting Method	Properties	Applications
Hamming code	<ul style="list-style-type: none"> • Corrects all single-bit errors • Can be modified to correct 2- or 3-bit errors • May fail to detect some error combinations 	<ul style="list-style-type: none"> • Reliable network links • Computer memory
Golay code	<ul style="list-style-type: none"> • Perfect Golay code encodes 12 bits into 23 bits, denoted by (23, 12) • Corrects all errors with 3 bits or less • Extended Golay code (with 1 additional parity bit) can correct errors as long as 4 bits 	<ul style="list-style-type: none"> • Because of low latency and short code word length, usually used in real-time applications and radio communications • Packet data communications • Mobile and personal communications • Radio communications • NASA deep space missions (Voyager 1 and 2) Communications
BCH code	<ul style="list-style-type: none"> • BCH code of length $n = 2^m - 1$ with generator polynomial with roots a^1, a^2, \dots, a^{2^t} can correct t-bit errors 	<ul style="list-style-type: none"> • Used in digital communications and mass storage
Reed-Solomon code	<ul style="list-style-type: none"> • Code word has n data bits and k check bits • Errors up to $(n - k)/2$ can be corrected • Ensures high-quality throughput in real time 	<ul style="list-style-type: none"> • Storage devices such as CDs and DVDs • Mobile communications • Digital communications over noisy channels

(continued)

Table 5: (Continued)

Convolution code	<ul style="list-style-type: none"> • Used on data stream rather than data blocks • Previous bits are used to encode following bits in data stream • Encoded using finite state machines; decoded using Viterbi algorithm • Computation-intensive, hence more difficult to implement but extremely powerful error-correcting capabilities 	<ul style="list-style-type: none"> • Usually used where bit-error rate is relatively high and retransmission is not feasible such as satellite and deep space communications
Turbo codes	<ul style="list-style-type: none"> • High-performance error-correcting code based on convolution code • Encoded data stream consists of: 3 subunits: payload data, parity for data, and parity bits for known permutation of data. • Both parities are calculated using convolution code 	<ul style="list-style-type: none"> • Usually used to achieve maximum data transfer over noisy bandwidth-limited channels • Deep space and satellite communications • 3G wireless networks

CONCLUSION

Data communication is straightforward, but there are many factors that can corrupt information as it travels along a transmission media. To ensure data integrity, many preventive measures can be taken. For instance, shielding counteracts the effects of cross talk, impulse noise, and induced noise. Other specialized filters remove other types of noise such as white noise. Amplifiers reduce the effect of attenuation and so forth. Despite all of these preventive measures, errors can still creep into data. As a result, the integrity of data cannot always be ensured. To achieve reliable data transmission, error-detection and error-correction schemes are needed.

As the term implies, *error detection* is used to detect errors in transmission. Techniques include parity check, LRC, block sum check, CRC, and checksum. Once an error has been detected, there are two options: correct it or request retransmission. Retransmission protocols used by the data-link layer include *positive acknowledgment with retransmission* (PAR) or *automatic repeat request* (ARQ), and *sliding window* protocols (*go back n* and *selective repeat*). There are many techniques that can be employed to correct errors, including the popularly used Hamming code.

GLOSSARY

Attenuation: The loss of energy when a signal travels through a medium.

Block sum check: Modification of LRC to allow detection of some burst errors.

Checksum: Error checking based on 1's complement addition.

Code word: Used to define a data unit together with its redundancy bits.

Cyclic redundancy check (CRC): Error checking based on polynomials. Most reliable error-detecting method.

Distortion: Often caused by the different speeds associated with each component of a complex signal.

Hamming code: Code that makes use of multiple even parity check bits inserted at strategic positions in the transmitted data unit to correct single bit errors.

Impulse noise: Noise caused by spikes.

Induced noise: Noise caused by electromagnetic interference.

Longitudinal redundancy check (LRC): Modification of parity check to allow detection of double bit errors.

Parity: Even and odd parity; simplest way to check for single bit errors or errors where the total number of bits is odd.

Redundancy bits: Bits added to check for or correct errors. They do not form part of the original data.

White noise: Usually random; also referred to as background noise.

INTRODUCTION

Routers are networking devices that operate at the network layer (layer 3) of the OSI reference model. They are used to connect two or more computer networks. In the simplest case, a router consists of a computer with at least two network interfaces that support routing protocols. The main function of routers is to route packets across the networks from a source to a destination. Two processes inside the routers accomplish this function. The first process is *route processing*, or determining the best route to move packets from source to destination and filling this routing information into a routing table. The routing process is independent of the packet arrivals; it is performed by running the routing protocols periodically or in an event-triggered manner. By exchanging routing information with other routers in the network, each router is capable of constructing a complete picture of the entire network topology and thus finding the optimal routes to a destination.

The second process is *packet forwarding*, or looking up in the routing table to find the particular outgoing interface to use for each incoming packet, and moving the packet from the incoming interface to the outgoing interface. The forwarding process happens every time a packet arrives. When a router receives a packet, it uses the information contained in the packet header and the information contained in the routing table to decide whether to forward the packet to an appropriate outgoing interface or to respond to the packet for local processing. When the router responds to the incoming packet, it will behave as an end system rather than as an intermediate system. When the router decides to forward the packet, the packet is forwarded from the arriving interface to the outgoing interface through the switching backplane. The packet then is sent to the next host, which may or may not be the ultimate destination. If not, the next hop is typically another router or switch. As the packet moves across the network, its physical address changes from hop to hop, but its protocol address remains the same, which is the protocol address of the ultimate destination host.

A general purpose processor usually controls the operation of routers. Although both route processing and packet forwarding can also be implemented in the general purpose processor, advanced routers separate these processes by employing a number of distributed processors that are capable of performing specific tasks. Furthermore, modern high-performance routers use special high-performance network interfaces that include an onboard forwarding engine to speed up operation.

Routers are deployed at every level in the Internet. Routers in small office and home offices connect a small number of users to an *Internet service provider* (ISP). Routers in enterprise networks connect multiple *local area networks* (LANs) within the enterprise and ultimately connect them to the Internet backbone. Routers in the Internet backbone link together ISPs and enterprise networks with long-distance trunks. Because computer networks come in a variety of sizes and architectures, routers need to be designed specifically to meet these needs and be flexible enough to allow for changes in order to provide diverse services. The design of routers has an enormous impact on every aspect of the router's performance and consequently the network's performance.

ROUTER HARDWARE COMPONENTS

We start this section by introducing the main hardware components in traditional or first-generation routers. As shown in Figure 1, a traditional router is a rather simple piece of equipment with the following hardware components: network interfaces, shared bus, and routing processor.

Network Interfaces

Network interfaces are the hardware components that connect a router to the network and perform in- and out-bound packet transmission to and from their immediate neighbors, which could be routers, switches, or normal hosts. Typically, two different modules—namely, input port card and output port card—perform the functions of

Figure 1: Hardware components in a traditional router

network interfaces. In Figure 1, each interface has one input port and one output port. In practice, multiple input and output ports are often gathered together on the same network interface. The protocols running on each interface are determined by the network that connects each interface. Figure 2 illustrates the main hardware modules on each port.

Next, we introduce the main functions performed on each input and output port with a focus on the layer 3 processing.

Input Port

The primary functions performed on the input port are verifying the integrity of the packet, modifying the packet header, and looking up the routing table to obtain the next hop information so that the packet can be forwarded to the appropriate output port. In particular, the following series of actions are performed on a packet's arrival.

IP Packet Verification. After passing the checking at layers 1 and 2, the packet is verified at layer 3 by checking the fields of version number, header length, and header checksum in the packet header. Only well-formed packets are placed in a shared memory pool for further processing; otherwise, the packet is discarded and an ICMP error message is returned to the original source.

An Interrupt Called on the Routing Processor. The routing processor is notified of the arrival of the packet. The routing processor then records the packet's location in memory and schedules a process to find out to which output port the packet should be sent.

Destination IP Address Parsing and Table Lookup. The destination address of the packet is extracted. If the packet is for this router (i.e., the destination address matches a router interface address), it is forwarded to the appropriate higher-layer protocol such as TCP. If it is for a remote host, then the routing table is examined to find the outgoing interface. The selected interface corresponds to the entry where the largest number of leading address bits match the destination address. In the case when the router does not know how to forward the packet, the packet is typically dropped. If the packet has multiple destinations (i.e., it is a *multicast* packet), then a set of output interfaces is chosen.

Packet Lifetime Control. The packet is discarded if the value of the *time to live* (TTL) field has decreased and is zero or negative. In this case, an ICMP error message is sent to the original source. The packet lifetime control is one effective approach to preventing packets from wandering around forever.

Handling Standard IP Options. Some packets require IP options handling such as *source routing* (the originating host chooses the route to the destination), *security* (the originating host specifies how secret the packet is), and *time stamp* (which makes each router append its own address and time stamp).

Handling Other Options. In reality, routers also need to handle *tunnels* (packets carrying other packets inside them), *network address translation* (i.e., map local private IP addresses to public global IP addresses and vice versa), *quality of service* (QoS) features (such as priority for some packets), and *packet filtering* (filtering packets according to security rules by looking at the packet's contents).

Packet Forwarding. At this point, the packet is ready to be forwarded to the output port. When all packets ahead of this packet in the transmit interface queue have been sent, the interface controller transmits the packet. If the packet has multiple destinations (multicasting), one copy is transmitted to each of the destined output ports. The arriving interface then interrupts the routing processor to tell it that the packet has been sent. The memory buffer is now freed by returning it to the set of buffers available for new arriving packets.

Figure 2: Network interfaces

The processing described above is known as *basic forwarding*; all packets are processed following the same procedures. In reality, however, many packets are sent by the same source to the same destination. In this case, once the first packet has been processed and forwarded, the router understands the way to forward all successive packets to the same destination. Therefore, the router stores the forwarding decision after it has been made. Using the *cached* information (destination address, port number, and any other necessary details), the forwarding process can be faster. This is known as *fast forwarding*. With fast forwarding, a packet is handled immediately using an entry in the fast-forwarding cache without scheduling an interrupt to the routing processor. Just like any other caching system, it is unwise to keep the cached routing information for too long. Changes in network conditions require invalidating the entries in the routing table and, accordingly, the fast-forwarding cache. Thus, fast forwarding is highly effective at the edge of networks or within private networks (where there are comparatively few destination addresses and routes). It provides little advantage at the center of networks.

Output Port

The primary functions performed at the output port are to construct the outgoing packets and transmit them to the outgoing links. In particular, the following series of actions are performed on the output port.

Fragmentation. The output port checks the *maximum transfer unit* (MTU) of the output network interface. Packets larger than the interface's MTU must be fragmented into a suitable size for transmission. If a packet is received that has the *do not fragment* (DF) bit set, then the packet should not be fragmented but instead discarded if it is larger than the MTU of the output network interface.

Checksum Recalculation. Because at least the TTL field always changes from hop to hop, the header checksum needs to be recalculated.

Destination Physical Address. By looking in the *address resolution protocol* (ARP) cache, the medium access control address of the next hop router is found. If there is no such entry, an ARP request can be sent. The physical address is then added, and the packet is linked into the list of packets to be sent in the appropriate output interface.

Packet Scheduling. A packet is typically placed in a queue waiting for transmission. If there is a single *first in, first out* (FIFO) queue, then a simple first-come-first-service policy is used. More complicated packet-scheduling algorithms are needed to allocate the link bandwidth and service order among users if there are multiple queues on the output port. More information about packet scheduling can be found in "Packet Switching".

Packet Transmission. The packet is finally sent to the outgoing link with the physical address set to the next hop

router. When complete, the buffer (memory) allocated to the packet is released, and it may be used to store a new received packet.

Shared Bus

The shared bus connects the router's other components. It serves as a switching backplane to forward packets from the input interface to the output interface. A new arriving packet is first moved from the input interface buffer, across the shared bus, to the *central processing unit* (CPU), where the routing decision is made. The packet then is transferred across the bus again to the output interface buffer, where it waits to be transmitted to the link. Apparently, only one packet at a time can be transferred over the bus. Moreover, as the number of interfaces increases, the arrival rate of packets increases, or both, the demand on the bus grows.

In addition to the shared bus architecture, traditional routers also employ another similar architecture named *shared memory-based backplane* as shown in Figure 3 (Kurose and Ross 2003).

In this system, incoming packets are written into the shared-memory pool. The routing processor then reads the header information from the memory and makes the routing decisions. The switching operation therefore consists of removing a pointer from the receiving queue and copying the value of the pointer to the appropriate transmit queue. The memory would have to be a two-port design that allows simultaneous reads and writes at different memory addresses at the same time. Reading only the header saves a great deal of activity on the bus, but the system must be designed so that the network interfaces know which headers have been updated so they can remove the packets from memory and forward them to the next hop. As the link speed and router size increase, the shared memory and CPU may become the performance bottleneck and make the switching capability limited.

Both the shared-bus and shared-memory architectures make multicasting much simpler than other architectures. As packets move on the bus, it is simply a matter of informing multiple network interfaces to take packets off the bus and send them out to their respective links.

Figure 3: Shared memory-based backplane

Routing Processor

The routing processor executes routing protocols, constructs and maintains the routing table, and performs the forwarding function. In addition, the routing processor also performs management functionalities such as link up and down management and system control. For example, it responds to any *Internet control message protocol* (ICMP) messages it receives, and it may generate ICMP error messages when error events are detected (such as a packet received that cannot be routed because the address is not known). These functions do not apply to every packet; therefore, they are performed relatively infrequently.

The routing protocols define the information from the packet that a router uses to find a particular entry in the routing table, as well as the exact procedures that the router uses for finding the entry. The forwarding function consists of a set of algorithms that a router uses to make a forwarding decision on a packet.

The routing table contains lists of IP destination addresses and the appropriate network interfaces to be used to reach the destination. A default entry may be specified for all addresses not explicitly defined in the table. Figure 4 shows the routing table for the given network. The structure of the routing table varies, depending on the routing protocol used. The minimum information included in the routing table is a triple of $\langle \text{Destination, Next hop, Metric} \rangle$. Here the metric specifies the cost of reaching the next host. It could be as simple as a single measure (such as hops, physical distance, bandwidth, or measured delay) or as complex as a function of hops, physical distance, bandwidth, communication cost, average traffic load, and measured delay. Figure 4 illustrates the structure of a routing table using the *distance vector routing* algorithm. For clarity, a single measure (hops) is used as the metric.

The routing table is constructed by using information supplied when the router is configured (installed). Although the routing table may be configured manually, it is usually configured automatically using a routing protocol. The routing protocol allows a router to periodically exchange information to all of its neighboring routers about the contents of its own routing tables. After a period of time, the router becomes aware of all the possible

routes to reach each end system connected at any point in the network. It therefore adds the information to its own routing table about the other routers to which it is connected, building a picture of how to reach other parts of the network. Routers near the center of a network generally have enormous routing tables, whereas those nearer the edges have smaller tables.

There are two basic approaches to construct a routing table (Comer 2004 “Computer networks”): static routing and dynamic routing.

Static Routing

In static routing, a program or network administrator computes and installs routes to be followed when a router boots; the routes do not change. Although this approach is simple, it is not flexible enough to allow change in routes based on dynamic network conditions.

Dynamic Routing

In dynamic routing, a program builds an initial routing table when a router boots; the program then updates the table as conditions in the network change. This approach provides the capability for a network to handle problems automatically. The two well-known routing algorithms for distributed route computation are the *distance vector algorithm* and the *link state routing algorithm* (Tanenbaum 2003).

Static routing is applicable when network topologies do not change significantly and route calculations can be performed offline. Typically, however, the dynamics of networks necessitate more sophisticated algorithms to allow routers to adapt to rapidly changing network conditions. For interior routing within each network that is controlled by a common network administrator (such a network is often referred to as an *autonomous system*), *open shortest path first* (OSPF) is the predominant protocol. OSPF operates by abstracting the autonomous system into a directed graph. In the graph, nodes represent routers or LANs, and arcs represent the lines connecting routers and LANs. Each node measures the cost (distance, delay, bandwidth, etc.) to each of its neighbors and send its updates either to all other nodes in the system by

Figure 4: Routing table

broadcasting or to certain nodes in the system by multicasting. Eventually, every node in the system knows the complete picture of the entire system and thus is able to compute the shortest path to every other node.

Although OSPF is the recommended routing protocol within an autonomous system, a different protocol—*border gateway protocol* (BGP)—is frequently used between autonomous systems. BGP is fundamentally a distance vector protocol. It operates by maintaining the cost to each destination and keeping the track of the path used. Instead of just telling each neighbor its estimated cost to every other destination, each BGP router tells its neighbors the exact path it is using to reach the destination. BGP routers communicate with each other by establishing TCP connections and send updated router table information only when one host has detected a change.

Another important feature of BGP is that it is a policy-based routing protocol. Typical policies involve political, security, and economic considerations (Metz 2001; Tanenbaum 2003). For example, a corporate autonomous system might want the ability to send and receive packets from any other network. However, it might not want to deliver packets originating in one foreign autonomous system and ending in another foreign autonomous system, even though it is on the shortest path between the two autonomous systems. It should be noted that many other routing protocols, such as *routing information protocol* (RIP) and *enhanced interior gateway routing protocol* (EIGRP), are also widely used in practice. More information about routing protocols can be found in Chapter 4.

ROUTER DESIGN ISSUES

The first generation of routers (Figure 1) was based on software implementation on a single general-purpose CPU. They benefited from the ability to be easily upgraded and modified. However, this simple architecture inevitably yielded low performance because of the following reasons. First, the overall processing speed is definitely limited by the single CPU. Second, the software implementation of routing is inefficient because most of the operations could be conveniently implemented in hardware. Third, for the shared-bus architecture, packets need to travel twice through the shared bus. This brings significant overhead and delay.

Next we introduce the design goals and techniques for modern high-performance routers.

Design Goals

High-performance routers are designed in an attempt to achieve the following goals:

High Throughput

Throughput is the number of packets the router can forward each second. This defines the aggregate packet-forwarding capacity of the router. Factors that affect throughput include the traffic model, buffer management, and packet scheduling.

Low Latency

Latency is the amount of time from the moment a packet leaves the outgoing interface to the moment a

packet arrives at the incoming interface. This time is determined by several factors, including the packet-processing time, routing table lookup time, calculations of routes, queuing time, and transmission time.

High Scalability

Scalability is the number of input and output ports the router can support with a good performance. It can be measured in terms of both the rate of increase in cost and the maximum possible router size.

High Reliability

Reliability is the total number of failures regardless of whether the failures result in router downtime.

High Availability

Availability is the percentage of time that the router is operating—that is, the total time the router is operational divided by the total time elapsed since the last failure.

Low Cost

The overall cost of a router is proportional to the number of ports, which in turn depends on the amount and kind of memory it uses, the processing power, and the complexity of the communication protocols used between the components.

Design Techniques

The techniques to achieve the above goals are summarized as follows.

Hardware Implementation

More and more of the packet-forwarding functions are performed in hardware. The improvement in the integration of CMOS technology has made it possible to implement a large number of functions in *application-specific integrated circuit* (ASIC) components.

Parallelism

Separate banks of forwarding engines and port cards are interconnected by *switching fabrics* (SFs) to either achieve higher performance or allow the use of lower-cost components.

Distributed Forwarding Decision Making

The forwarding decision can be made locally on the interfaces. This leaves the routing processor to focus on the overall system management rather than on packet processing.

Flexibility

Although switch-based fabric (hardware) has been widely employed, network processor-based routers have also attracted attention for their flexibility and active routing capabilities.

Quality of Service

Advance queuing and scheduling algorithms make it possible to provide differentiated quality of services.

EVOLUTION OF ROUTER ARCHITECTURES

Although some first-generation routers cache the routing decisions on each interface, the overall performance is still significantly limited by the central CPU and shared medium. Over the last decades, the evolution of router architecture has experienced several generations as follows.

Shared Processor-Based Architecture

As shown in Figure 5, in addition to the traditional routing processor, there are multiple distributed processing units (CPU and memory), and they are connected to network interfaces through the shared bus (Puzmanova 2002).

Each processing unit is associated with a group of interfaces and handles all packets received by the group of interfaces. In this design, an arriving packet could be sent to the available distributed CPU instead of the central routing processor. This dramatically reduces the load that would burden the routing processor. In addition, packets from the same flow (a stream of packets that have the same source and destination) could be always sent to the same CPU to speed up the process.

Dedicated Processor-Based Architecture

As shown in Figure 6, in dedicated processor-based architecture, each interface is equipped with a dedicated forwarding processor.

Figure 5: Router with shared processor

Figure 6: Router with dedicated processor

The forwarding processors do not take part in route processing; instead, they periodically receive all routing information from the router's routing processor. In doing so, a shadow copy of the routing table is stored on each of the forwarding processors. With local copies of the routing table, the forwarding decision can be made locally without invoking the routing processor. This approach allows the forwarding processor on each interface to handle large numbers of destination IP addresses, even when there are large numbers of route changes. It therefore scales well to core routers and is used in high-speed routers.

Switch-Based Architecture

The performance of the dedicated processor-based architecture is limited by the speed of the general purpose CPU and the shared bus. In the switch-based architecture (Figure 7), there are two major innovations.

First, the general purpose CPU is replaced by a specially designed forwarding engine. An appropriate ASIC is designed for each protocol processing task and then replicated on each network interface (Awewa 1999). The second innovation is that the shared bus is replaced by a crossbar switch fabric (McKeown 1997; Partridge et al. 1998). Hence all input and output ports are fully interconnected. A transmission path is dynamically configured between an input and an output. Therefore, multiple packets can be transmitted across the fabric simultaneously.

The performance of the switch architecture shown in Figure 7 can be further improved by deploying parallel technique in the implementation of forward engine and switch fabric. Figure 8 depicts the architecture of the forwarding engine where parallelism is achieved by partitioning forwarding functions among five different processors or ASICs (Kumar, Lakshman, and Stiliadis 1998). Because it performs only one type of function, each processor or ASIC needs only access the data associated with a particular function. Thus, the memory required is much smaller and can be more quickly acquired.

The performance of the switch-based router can also be boosted by using multiple crossbar switches in parallel

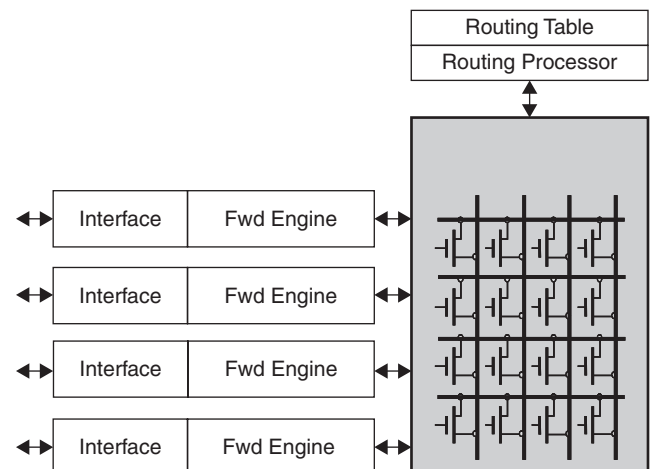

Figure 7: Router with forwarding engine and switch-based fabric

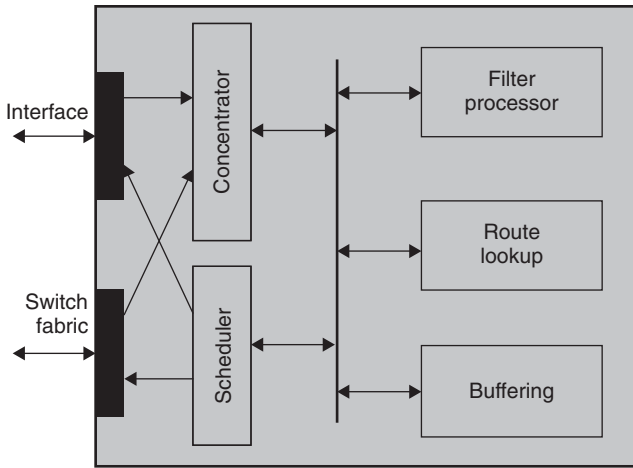

Figure 8: Parallel implementation of forwarding engine

Figure 9: A four-way parallel crossbar switch

(McKeown 1997). Figure 9 demonstrates a switching backplane that has four parallel crossbars.

In Figure 9, during each time slot, all of the crossbar “slices” are set to the same configuration, presenting a four-bit wide bus from each interface card to the switch core. A centralized scheduler connects to each interface card and determines the configuration of the crossbar switch at each time slot.

NEW DEVELOPMENTS IN ROUTER DESIGN

With the transformation of the Internet into a ubiquitous commercial infrastructure for conducting business, research, education, and entertainment, the ability to guarantee QoS and provide diverse services has become as important as providing massive bandwidth. Unfortunately, the bottleneck of the Internet has moved from links to routers with the rapid provisioning of higher performance links and the introduction of wavelength division multiplexing (Chao and Degermark 1999). As an effort to alleviate the bottleneck, new developments in router design have emerged dramatically. The differentiated service architecture (Blake et al. 1998) has been designed to provide a simple, easy-to-implement, low-overhead tool to support applications with diverse QoS requirements. In this architecture, the administration defines a set of

service classes, each corresponding to a certain level of QoS requirements. When a user signs up for the differentiated service, its packets are classified as one type of class by using the current *type of service* field (IPv4) or *traffic class* field (IPv6). Routers within the differentiated service domain then use this field to provide differentiated quality of services. At the routing protocol side, *IP switching* (Newman et al. 1997) and *multiprotocol label switching* (Rosen, Viswanathan, and Callon 2001) have been proposed to speed up the switching and routing process. In the rest of this section, we present the new hardware developments.

Buffer Management

Buffers are critically important hardware components in modern routers. Given the fact that only one packet can be transmitted to the external link at any cycle, routers need buffers at the output side to temporarily store the backlogged packets in the following scenarios: (1) the network is congested and thus the packet transmission speed must slow down, and (2) multiple packets are forwarded to the same output port at the same cycle. Similarly, routers need buffers at the input side for the following reasons. Because of the stochastic nature of the packet arrival process and the heterogeneous nature of connected links, it is likely that multiple input ports have packets destined to the same output port at the same cycle, a phenomenon called *output contention*. Given the current technology, the switch fabric is not able to forward all of the contending packets, so the remaining packets must be stored at the input port. As more and more packets are backlogged at the input port, packets with different destinations start to contend for the resource within the switch fabric, a phenomenon called *input contention*. Moreover, contention may also occur within the switch fabric, a phenomenon called *internal contention*. All of these contentions need to be solved by placing buffers at the appropriate location.

Next we briefly introduce the three basic queuing schemes: output queuing, input queuing, and virtual output queuing.

Output Queuing

In output queuing, buffers are allocated at the output ports. Typically, they are organized as multiple queues to support multiple classes of services. Incoming packets are immediately forwarded to the appropriate output port and stored in one of the queues. Because packets are queued directly at the output links to which they must be transmitted, the output links will never suffer from the starvation. By employing one of the weighted fair queuing policies (Zhang 1995), the best delay throughput performance can be easily obtained. To implement the output queuing scheme, however, the switch fabric must operate N times faster than the external links in a router of N ports. This is impossible for routers with more ports or higher link rates. As an example, consider a router with 16 ports operating at 2.5Gbps. One path in the switch fabric must be able to transfer at $2.5 \times 16 = 40$ Gbps to accommodate the worst case. This requirement is too high for the implementation of both fabric and memories.

Input Queuing

In input queuing, buffers are allocated on the input ports. Traditionally, the entire buffer was organized as one queue. If more than one packet is destined for the same output, only one packet can be transmitted. The other packets are temporarily buffered at the input ports. For routers with Gigabit links, the switch fabric needs to operate only slightly faster than the links. Although the speed constraint of fabric is removed, the router performance is significantly degraded due to the *head of line* (HOL) blocking (Karol, Hluchyj, and Morgan 1987). Moreover, it is difficult to control the packet delay bounds resulting from the input contention.

Virtual Output Queuing

The widely employed queuing policy for modern routers is *virtual output queuing* (VOQ). In a VOQ-based router, each input port organizes the buffer into N logical queues, each associated with an output port. It has been shown that VOQ is able to provide a maximum throughput of 100 percent (McKeown et al. 1999). To better improve the link utilization, buffers are allocated on both input and output sides. This is called *combined input and output queuing* (CIOQ) as shown in Figure 10.

In Figure 10, the VOQ scheme is employed on the input port, and a single FIFO queue is employed on the output port. It has been proved that a router with CIOQ behaves identically to a router with output queuing if the fabric of CIOQ router operates $2 - 1/N$ faster than the external links (Chuang et al. 1999).

Multicast Queuing

To efficiently support multicast traffic (i.e., traffic with multiple destinations), special attention is needed in the queuing design. Simply considering multicast as a special case of unicast does not allow queuing to be scalable. For example, VOQ is commonly believed to be the best queuing scheme for unicast traffic but is not suitable for multicast traffic. For multicast traffic, in order to implement the VOQ-based architecture, in total $2^N - 1$

queues are needed at each input port. This is impractical for large routers. One simple queuing policy for multicast traffic is to allocate one queue at each input port (Hui and Renner 1994). Given independent and identically distributed traffic and a random packet-scheduling algorithm, the throughput λ versus fanout f (the number of destinations) is given as follows:

f	1	2	4	8	16
λ	0.59	0.69	0.78	0.85	0.90

An advanced multicast queuing policy allocates multiple queues at each input port (Bianco et al. 2003; Song et al. 2005). Because more queues provide more scheduling spaces, the throughput can be increased significantly. Under the same traffic and scheduling policy as in Hui and Renner (1994), the throughput λ versus fanout f is given as follows when three queues are allocated at each input port:

f	1	2	4	8	10	16
λ	0.78	0.84	0.88	0.92	0.93	0.95

Before we conclude the topic of buffer management, it is important to note that other aspects of buffer management deserve equal attention in router design. These include the buffer's speed and size, both of which grow linearly with the external link rate. To handle the speed problem, one solution (Iyer, Kompella, and McKeown 2002) is to take advantage of the density of DRAM and the speed of SRAM. Specifically, a small fast SRAM holds (caches) the heads and tails of queues, allowing arriving packets to be written quickly to the tail and departing packets to be read quickly from the head. The large DRAMs are used for bulk storage, holding the majority of packets in each queue that are at neither the head nor the tail. A memory manager shuttles packets between the SRAM and the DRAM. To handle the

Figure 10: Combined input and output queuing scheme

size problem, one suggestion (Villamizar and Song 1994) is that the capacity of a port should have enough buffers to hold as many packets as could pass through the buffer in end-to-end round-trip time.

Active Networking

Active networking is a new communications paradigm for data networks. With active networking, the network is no longer viewed as a passive move of bits but as a more general computation engine: Packets injected into the network may be modified, stored, or redirected as they are being transported. To do this, routers are expected to perform more customized computing functionalities that could be customized on a per-user or per-application basis. For example, a user of an active network could send a customized compression program to a router within the network and request that the router execute that program when processing the user's packets.

There are two primary approaches to implement the active networking (Tennenhouse et al. 1997). In the first approach, users send a trace program to each router and arrange for the program to be executed when their packets are processed. The second approach is that packets themselves contain the program that can be recognized and executed by routers. The fundamental difference between these two approaches is the *out-of-band* (first approach) or *in-band* (second approach) transmission of the executable code.

With the wide deployment of active networking, more and more active services are becoming standard services shared by many users and applications. As a result, advanced router architectures include the use of *plug-ins* to dynamically reconfigure the router (Decasper et al. 2000). Plug-ins are basically specialized blocks that perform certain tasks. Because a router must be able to handle many different types of traffic, plug-ins provide a way to dynamically scale the amount of processing that has to be done on a packet to provide the most efficient packet handling possible given a set of plug-ins. When a special packet is detected and it is determined that a plug-in is needed, the plug-in management system loads the plug-in and reroutes the packet to the plug-in. Plug-ins may also work with other plug-ins to fully process packets. The strength of a plug-in is its ability to be removed from the processing chain and dynamically work together with other plug-ins. After these plug-ins are installed, subsequent packets that require similar processing can make use of the plug-in more quickly than when they were first invoked.

As a note to active networking, care must be taken when deploying the active services. Computing functions should be placed in the network only if they can be cost-effectively implemented there (Bhattacharjee, Calvert, and Zegura 1997). The semantics of any active features must be carefully constrained so that interactions among different users can be predicted by a user who is using the active service and functions (Reed, Saltzer, and Clark 1998). Moreover, large-scale deployment of active services involves significant challenges in interoperability, security, and scalability.

Network Processor

Modern routers require the flexibility to support new protocols and network services without changes in the underlying hardware components. However, the traditional general purpose processor-based routers are not applicable for modern high-speed networks because of their low performance. The continuing advances in integrated circuit technology are making it possible to implement network processor-based router architecture. A network processor is a special purpose, programmable hardware device that combines the low cost and flexibility of a *reduced instruction set computer* (RISC) with the speed and scalability of ASIC chips (Comer 2004 "Network systems"). Network processors are designed to be implemented on a single chip that integrates many small, fast processor cores, each tailored to perform a specific networking task.

The first step in developing an architectural design of the network processor requires an identification of important functions. These functions are then partitioned into two groups. The first group—called *ingress*—focuses on arriving packets; the second group—*egress*—focuses on departing packets. To implement both ingress and egress, specific software architecture needs to be implemented. Figure 11 depicts the software architecture of the network processor. A classifier (C) first reads the packets from an input port. The forwarder (F) is selected based on certain fields in the packet header. Each forwarder then procures packets from the input queue and executes some predefined function to the packet; the modified packet is then transmitted to its output queue. The transformation of packets occurs in the forwarders. The output scheduler (S) selects one of the nonempty output queues and transmits the associated packet to the output port.

Network processors are flexible to maintain low overall cost. They are not limited to a particular protocol or particular layer of the stack. This results in the usage of network processor in any layer of the stack in applications

Figure 11: Software architecture of network processor

such as a layer 2 bridge, a layer 3 router, a layer 4 splicer, or a layer 5 load balancer. Because a network processor offers the ability to program and change its behavior, the system that uses network processors can be designed and implemented more quickly because no changes are required in hardware.

Secure Routing

Many of the protocols that are in widespread use were designed with the assumption that no users on the network are malicious. Gateway routers do not typically verify the source address of an incoming packet, making it easy to “spoof” packets. Routers rely on both temporal and spatial locality for doing fast routing table lookup, but an incoming stream of packets with randomly generated destination addresses can cause worst case table lookup latencies and grind routers to a halt. For this reason, there is another table called the *filter table* along with the routing table. The filter table is usually manually configured and contains a list of addresses and other packet header details that, if they match a received packet, will cause the packet to be either discarded by the network interface immediately or forwarded directly to the routing processor for further processing. This may be used to deny access to particular protocols or to prevent unauthorized packets being forwarded. More information about network security can be found in the *Handbook of Information Security* (Bidgoli 2006).

CONCLUSION

In this chapter, we studied routers from the hardware perspective. We introduced the main hardware components and their functions, and we reviewed the evolution of router architectures. For each type of architecture, we analyzed the strengths and weaknesses as well as the design issues. To support the ever-growing services supported by the Internet, specialized network processors are being developed to address the specific needs of network activities and perform active networking by using plug-ins. As Internet traffic continues to grow, we anticipate that the newest development in router design will be to create special purpose routing control platforms to facilitate routing traffic. In addition, because the computer networks come in a variety of sizes and architectures, routers need to be designed specifically to meet these needs and be flexible enough to allow for changes in order to provide diverse services.

GLOSSARY

Address resolution protocol (ARP): A protocol that maps an Internet protocol address to a physical machine address that is recognized in the local network.

Application-specific integrated circuit (ASIC): A microchip designed for a special application such as a transmission protocol.

Enhanced interior gateway routing protocol (EIGRP): A network protocol that lets routers efficiently exchange information. EIGRP evolved from interior gateway routing protocol (IGRP); routers using

either EIGRP and IGRP can interoperate because the metric used with one protocol can be translated into the metrics of the other protocol.

Head of line (HOL) blocking: A phenomenon that a blocked HOL packet prevents the packets behind it from receiving service. This happens because only the HOL packets can be transmitted.

Internet control message protocol (ICMP): A message-control and error-reporting protocol between a host and a router. It is also used to test the Internet.

Internet protocol (IP): A networking layer protocol by which packets are delivered from one computer to another on the Internet.

Open systems interconnection (OSI): A standard description or reference model for how messages should be transmitted between any two points in a communication network.

Router: A networking device that determines the next network point to which a packet should be forwarded toward its destination.

Routing information protocol (RIP): A widely used protocol for managing router information within a self-contained network such as a corporate LAN or an interconnected group of such LANs. It is one of several internal gateway protocols.

Switching fabric (SF): Combination of hardware and software that moves packets from the input ports to the output ports.

Virtual output queuing (VOQ): A queuing mechanism in which each input port organizes the buffer to N logical queues, each associated with an output port.

INTRODUCTION

Switches are frequently referred to as layer 2 devices because they principally operate at the data link layer of the *open systems interconnection* (OSI) reference model (Day and Zimmermann 1983). As one of the most important interconnecting devices in today's networks, switches are often used to connect multiple segments of a large *local area network* (LAN) in order to extend the length of the LAN and increase its effective bandwidth. The interconnection of switches provides a large-scale network without reducing individual end host performance. In addition, switches can be used to directly connect individual hosts to form a LAN. The main task of switches is to forward frames from the inbound link to the outbound link based on the information contained in the frames. In addition, switches also play an important role in network security and traffic management.

In a generic switch, the main hardware components include several line cards or interfaces, a high-speed switching fabric, and a control unit. The line cards connect the switch to other networking devices, which could be LANs, other switches, routers, or individual hosts. On each line card, there are several port cards with links running the appropriate layer 2 protocols to communicate with the port cards at the other end of the link. The switching fabric forwards these frames to the appropriate output ports. The forwarding process is guided by the forwarding table, which is constructed and maintained by the control unit. The control unit also performs management functions such as link up or down management, and system control. Advanced line cards may also have embedded memories and control units to perform local processing.

The architectures of the contemporary switches vary widely and evolve rapidly. As a result, many switches with diverse features appear on the market. Unlike the traditional switches that operate at layer 2, these switches operate at both layers 2 and 3. Some even have the capability of supporting multiple network paradigms such as *Internet protocol* (IP) networks and *asynchronous transfer mode* (ATM) networks. Therefore, the definition of the

switch has changed over time. Nevertheless, the fundamental functionalities of switches—interconnecting networking devices and forwarding frames—have never been changed. Based on this thought, we classify switches by two dimensions: communication spectrums and network paradigms.

In the remainder of this chapter, we first introduce the switch hardware components, some representative switch architectures, and switch performance metrics. We then present two types of switches: The first type is the LAN switch, which includes Ethernet switches and token ring switches. For both Ethernet and token ring switches, the *virtual LAN* (VLAN) switching capability is also discussed. The second type is the *wide area network* (WAN) switch, which includes packet switches and ATM switches. For both packet and ATM switches, the multicast switching capability is briefly studied. Finally, new switch architectures that require no speedup and support both unicast and multicast traffic are discussed.

SWITCH ARCHITECTURES

Hardware Components

As we mentioned earlier, all switches have conceptually the same hardware components: input port cards, output port cards, a switching fabric, and a control unit. As a matter of fact, a switch and a classic computer share many similar hardware components. A general purpose computer equipped with several network line cards and suitable software can provide the same function as a switch. The biggest difference, however, is that the general purpose computer performs switching more slowly than a switch because of the fact that all frames from different links must pass through a common I/O bus. Every frame crosses the I/O bus twice and is written to and read from main memory once. Therefore, the aggregate throughput is limited to either half of the main memory bandwidth or half of the I/O bus bandwidth. The aggregate throughput of switches can be significantly improved by employing a high-performance switching fabric and

Figure 1: The main hardware components of a generic switch

distributed processing facility. Next we introduce some representative switch fabric architectures. For simplicity, an $N \times N$ switch is assumed, which means there are an equal number of input and output ports.

Figure 1 shows the main hardware components of a generic switch. Depending on which type of device they are connected to, the input port cards perform totally different tasks. For example, if an input port card connects to an Ethernet LAN, then the main tasks of the port card are to build and maintain the *forwarding table* that maps between the *medium access control* (MAC) addresses and the output ports and to determine which output port a frame should be sent to. On the other hand, if an input port card connects to an ATM link, then the main tasks of the port card would be to set up and manage the *virtual path identifier* (VPI) and *virtual circuit identifier* (VCI) table and determine which output port a cell should be sent to. Nevertheless, many input port cards perform the same fundamental tasks as follows:

- provide a link enable and disable function;
- reformat a frame from the external format to the internal format;
- determine which output port or ports a frame should be sent to;
- buffer the frames that cannot be sent to the switch fabric at the current cycle (if there are multiple buffers on the input port card, then a scheduling algorithm is needed to determine which frame can be transmitted to the output port at the current cycle); and
- maintain configuration values, error flags, and statistics counters.

Similarly, the fundamental tasks of the output port cards are as follows:

- reformat a frame from the internal format to the external format;
- buffer the frames that cannot be transmitted to the link at the current cycle;
- determine by a scheduling algorithm which frame can be transmitted to the link at the current cycle if there are multiple buffers on the output port card; and

- maintain configuration values, error flags, and statistics counters.

The primary task of the switch fabric is to quickly forward frames from the input ports to the output ports. When a switch fabric receives a frame passed from the input port, it forwards the frame to the output port based on the information either contained in the frame or sent from a control unit. A simple switch fabric has only one stage, whereas a complex switch fabric may have multiple stages with each one having different functions.

Representative Switch Architectures

In this section, we introduce representative switch architectures that are used to build large-scale switches.

Shared-Memory Switches

In shared-memory switches, all input ports and output ports share the same memory (as shown in Figure 2). Shared-memory switches are also called shared-buffer switches, in which memories are organized as linked-list buffers. (There are four linked lists in Figure 2.) The switch operates as follows. Incoming frames are sequentially written to the appropriate locations of the shared memory. The memory addresses for writing incoming frames and for reading stored frames are provided by a central control unit (not shown in the figure). There are two approaches in determining how the entire memory is shared among the output ports. The first approach is *complete partitioning* in which the entire memory is divided into N equal parts and each part is assigned to a particular output port. The second approach is *full sharing* in which the entire memory is shared by all output ports without any reservation. In this design, mechanisms such as an upper and lower bound on the memory space are needed to prevent monopolization of the memory by any output ports.

The main advantage of shared-memory switches over other switch designs is that a much smaller memory is enough to achieve the same blocking probability (Walrand and Varaiya 2000). Because its memory space is shared among its switch ports, a shared-memory switch achieves a high buffer utilization efficiency (Tatipamula and Khasnabish 1998). Another advantage is that more complex memory-sharing schemes can be readily implemented to provide different levels of service and thus guarantee

Figure 2: The architecture of a 4×4 shared-memory switch

Figure 3: The architecture of a 4×4 crossbar switch

frame delay and frame loss ratio. In addition, shared-memory switches intrinsically provide good support for multicast traffic (Francini and Chiussi 2002). When a multicast frame arrives, only a single copy is stored in the shared buffer. The frame will then be read multiple times to different output ports (Saito et al. 1994).

The main limitation of the shared-memory switch is that the memory and the central control unit must run at least N times faster than the link speed. As the link speed and size increase, the shared memory and central control unit may become the performance bottleneck and limit the switching capability. A more promising design is to provide multiple paths between the input ports and the output ports. These paths operate concurrently so that multiple frames can be transmitted across the switch simultaneously. The total capacity of the switch is thus the product of the bandwidth of each path and the number of paths that can transmit frames concurrently. Switches based on this design, such as crossbar switches, are called *space-division switches*.

Crossbar Switches

In a crossbar switch, every input port has a connection to every output port. As shown in Figure 3, a crossbar switch consists of N^2 crosspoints. When appropriately configured, these crosspoints connect every input port to every output port, allowing N frames to be transmitted each cycle. To deal with the output contention that occurs when multiple frames are destined to the same output port, two approaches can be employed. In the first approach, a crossbar switch provides buffers on the output port cards. In the second approach, a high-performance central scheduler is used to configure the crosspoints (McKeown et al. 1997). Both approaches can greatly increase the aggregate bandwidth of the switch when implemented appropriately. Crossbar switches can be used as a basic switching element to construct a multistage switch such as a Benes switch (discussed later).

Crossbar switches hold the most promise because of their architectural simplicity, modularity, nonblocking structure, and good support of multicast traffic. However, the implementation complexity of crossbar switches increases as fast as N^2 , making crossbar switches impractical for switches with a many ports.

Knockout Switches

Knockout switches are one type of switch that has been designed to reduce the complexity of crossbar switches (Yeh, Hluchyj, and Acampora 1987). The complete connectivity between the input ports and output ports is accomplished by N separate broadcast buses as shown in Figure 4. The address filters identify the frames that have the right output port numbers. Given that the likelihood that all input ports send frames to the same output port is small, the concentrator at each output port fairly chooses l out of N frames destined for the same output port in a single cycle.

The fairness in choosing l out of N frames is achieved by having all of the frames against each other in a form of knockout tournament to select l winners from N contestants. It works as follows. The tournament has l sections,

Figure 4: The architecture of a 4×4 knockout switch

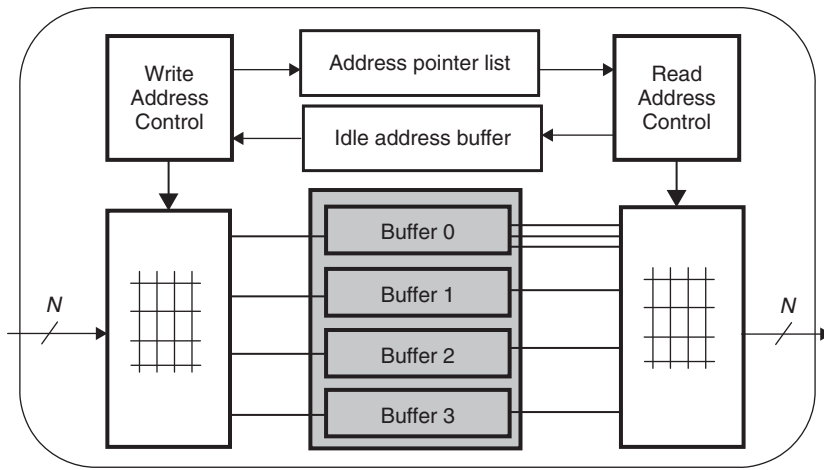

Figure 5: The architecture of a space-time, space-division switch

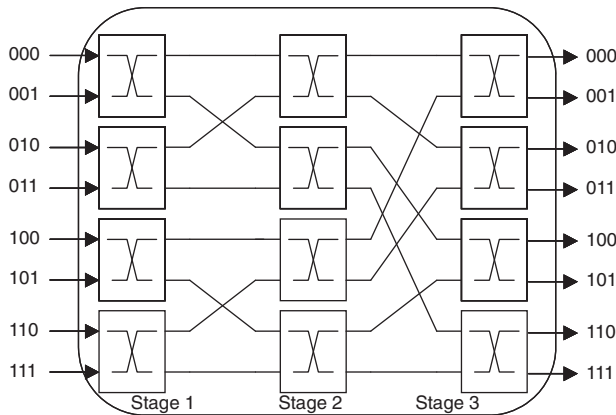

Figure 6: The architecture of an 8×8 Banyan network

each of which determines a winner. In the first section, a winner is randomly chosen. All the losers then go to compete in the second section. A winner is randomly chosen again. All of the losers then go to compete in the third section, and so on. Because only one winner is selected in each section, l frames are selected and all of the rest are dropped. The selected l frames go into the shifter, which distributes the frames uniformly over the multiple output buffers. Although knockout switches reduce the complexity of crossbar switches, they do increase the possibility of frames being dropped. In Figure 4, for example, if more than three frames are destined to the same output port in a cycle, then one of them will be dropped.

Another technique to reduce the complexity of crossbar switches is to combine the space-division and time-division techniques (Tatipamula and Khasnabish 1998). As shown in Figure 5, switches using this technique have a crossbar switch at both input and output ports. The two crossbars are connected by the shared memory. The *write address control* (WAC) extracts the header information from incoming frames and configures the input-side crossbar switch. The WAC also returns the frame location pointer to the *address pointer list* and receives the next available location from the *idle address buffer*. Similarly, the *read*

address control configures the output-side crossbar switch, returns the location pointers of transmitted frames to the *idle address buffer*, and receives the new memory location from the *address pointer list*. The memory operation speed is only required to be $k + 1$ faster than the link speed, where k is the speedup factor ($k = 3$ in Figure 5) of reading speed to writing speed in each cycle.

Self-Routing Switches

Self-routing switches use many small, interconnected switching elements (typically a 2×2 switch) in which frames find their own way through the switch fabric based on a sequence of local switching decisions made at each switching element (Peterson and Davie 2000). Figure 6 shows the architecture of an 8×8 Banyan network, where the port numbers are presented in binary format. The switch elements in stage 1 look at the most significant bit of the output port number and route the frame to the top output port if that bit is a 0 or to the bottom if it is a 1. Switch elements in stage 2 look at the second bit, and those in stage 3 look at the least significant bit. There will be no collision if the destinations of the frames are in an ascending order.

The main advantages for this type of switch are as follows:

- a linear complexity of $n \log_2 n$,
- a self-routing property (i.e., no control mechanism is needed for routing frames),
- a parallel structure (i.e., several frames can be processed simultaneously), and
- modular and recursive structures (i.e., large-scale switches can be built).

The main flaw of this type of switch is its internal blocking structure. This inevitably causes both internal and output contention and degrades the switch performance. Possible approaches to solve this problem are as follows.

- Allocate buffers within the switching elements to release contention. The buffer size could be just one.

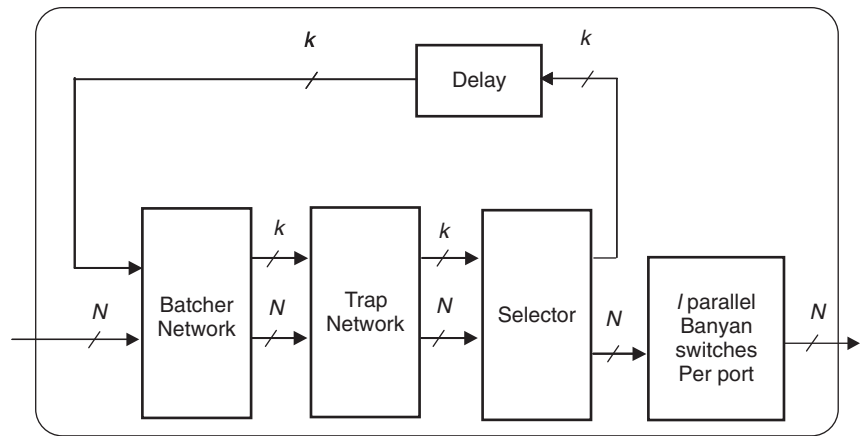

Figure 7: The architecture of the sunshine switch

- Add more stages to accommodate the output contention. Frames are examined at every augmented stage to determine whether they have arrived at their output ports. If so, they will be sent to the output link. Otherwise, they are routed to the next stage and will be examined again. This type of switch is called a *Benes switch*.
- Put a Batcher network in front of the Banyan network to permute frames into an ascending order. With a combination of Batcher and Banyan networks, the switch can deliver all frames to the destined output ports, as long as there are no frames heading to the same output port.

Sunshine Switch

To remove the restriction of no frames heading to the same output port required in Batcher-Banyan networks, the sunshine switch adds three components (Giacopelli et al. 1991) as shown in Figure 7.

The first component is a *trap network*. It identifies up to l frames that will be delivered to the same output port and marks up to k frames that need to be recirculated back to the Batcher network. The second is a *selector* that distributes those l frames to l parallel Banyan switches and sends back those k frames. The third component is a set of *delay* units that align the timing of the recirculated frames with the new frames. In addition, the sunshine switch uses l multiple parallel Banyan switches to allow up to l frames with the same output port destination at the same cycle. Using multiple, usually identical switching planes can significantly increase the switch throughput and reliability. This technique has been employed by several designs (Iyer and McKeown 2001 “Speedup”; Turner and Yamanaka 1998).

Performance Metrics

The switch performance can be measured by four metrics. The first is switch *throughput*, which reflects how many frames the switch can forward per second. It is usually measured in bits per second (bps). For comparison and theoretical analysis purposes, however, a normalized throughput is often used. In this case, a 100 percent throughput means that the switch has achieved the

maximum switching capability. For a switch with N inputs (outputs) and a link speed of s , the maximum throughput is Ns . The achieving throughput, however, is typically less than Ns because of output contention. Many queuing schemes and scheduling algorithms are designed to alleviate the impact of contention.

The second metric is *latency*, which reflects how long it takes on average to forward a frame from the input port to the output port. It is usually measured in milliseconds or microseconds depending on the bandwidth of the internal switch fabric and the external links. Several factors contribute to the overall latency, including processing delay, queuing delay, and forwarding delay. The third metric is *frame loss ratio*, which is measured as the percentage of the number of frames dropped to the total number of frames received. Buffer overflow is the primary reason for frame loss. The fourth metric is *complexity*, which may be quantified by the number of crosspoints, the buffer size, the speed of bit streams inside the switch, or the time running the scheduling algorithm. The main goal of a switch design is to achieve a high performance with desirable features such as good scalability (a function of N) and low cost.

LAN SWITCHES

LAN switches are the devices that connect multiple LAN segments. They improve the effective bandwidth by separating collision domains and selectively forwarding frames to the right segments. LAN switches offer plug-and-play operation and support dynamic switching. Most of them also have such network management capabilities as monitoring or remote monitoring. LAN switches are similar to bridges in that both operate in layer 2 of the OSI reference model. The primary differences between them are as follow.

- Switches provide much higher port density at a lower cost than do bridges (Kurose and Ross 2003). The higher port density results in several desirable features, such as a high aggregate forwarding rate, full duplex operation, and fewer users per segment. By operating

in a full duplex mode, switches can send and receive frames at the same time over the same interface. By having fewer users per segment, each host receives a dedicated bandwidth and does not need to contend with other hosts.

- Switches can be configured to make more intelligent decisions with respect to forwarding frames. For instance, switches typically provide a better quality of service than bridges by employing advanced queuing schemes and intelligent dropping policies. Most commercial switches can be configured to only accept frames from specific MAC addresses on specific ports.
- Switches have two switching modes: *store-and-forward* switching and *cut-through* switching; bridges only perform store-and-forward switching. Usually, cut-through is implemented entirely in hardware, and store-and-forward is implemented in software.

LAN switches make the forwarding decision by looking up the forwarding table maintained on each input port card. When a LAN switch is first plugged in, the forwarding table is empty. When a frame arrives at input port *i*, the switch uses a technique called *flooding* to send the frame to all output ports except port *i*. Meanwhile, the switch inspects the MAC address of the frame and learns that port *i* can be used in the future to forward frames with that particular MAC address. This process is called *backward learning*. The forwarding table is fully completed when all of the devices connected to the switch have either sent or received frames. After that, the switch determines which port to forward an incoming frame to by looking up the forwarding table.

The forwarding table is dynamically updated through the backward learning process. Unfortunately, a simple denial-of-service attack can quickly fill the forwarding table by generating tens of thousands of MAC addresses. When the table is full, the switch cannot learn any additional addresses, so the frames from new addresses are flooded throughout the entire LAN. This results in poor network performance. To prevent this from happening, security policies need to be imposed during the learning process. One approach is to provide the specification of the number of MAC addresses that can be learned by a particular switch port (Dubrawsky 2002). If the limit is exceeded, the switch will disable the port to protect the network.

LAN switches employ two switching modes: *store-and-forward* switching and *cut-through* switching. In store-and-forward switching, the switch first stores the entire frame in the input buffer and then processes the frame by doing error checking and looking up the forwarding table. The frame is discarded if its contents are compromised. If the outbound link of the frame is free, the switch sends the frame to that particular link via the switch fabric; otherwise, the switch temporarily stores the frame in the input buffer. In cut-through switching, the entire frame need not be stored in the input buffer. As long as the header information (e.g., the destination MAC address) of the frame is available, the frame is immediately forwarded to the output buffer. If the output link is free, then the frame can be immediately transmitted. There is

no error checking. Thus, cut-through switching usually causes less latency than store-and-forward switching but raises the risk of transmitting compromised frames.

The most widely employed LAN switches in today's networks are Ethernet switches and token ring switches. Based on the topology of switches, each can be further classified as follows (Puzmanova 2002):

- *backbone switches* that connect a LAN into high-speed protocols such as Gigabit Ethernet or ATM.
- *workgroup switches* that connect multiple segments that form a large LAN, and
- *desktop switches* that connect individual hosts for dedicated bandwidth.

Note that the difference between these three types of switches mainly lies in the interfaces. The interfaces in a backbone switch operate at especially high speeds, and the interfaces in a desktop switch operate at lower speeds. In fact, an advanced switch may have several different types of interfaces. This will become clear in the following discussion. A switch with different types of interfaces is called an *asymmetric switch* (Kane 2004).

Ethernet Switches

Ethernet switches are used to interconnect Ethernet LANs. Figure 8 illustrates the configuration of a switched Ethernet LAN with two Ethernet switches and seven hosts. The link speeds vary from, for example, 10 Megabits per second (Mbps) to 10 Gigabits per second.

The forwarding table in an Ethernet switch contains the following fields: MAC address, outgoing port number, and timer.

The MAC address refers to the destination address of the frame. The outgoing port number refers to which port should be used to transmit the frame to that particular MAC address. The timer indicates the age of the entry—that is, the association of the MAC address to the outgoing port number is only valid before the timer expires. The significance of the timer is used to accommodate the dynamic property of LANs in which links or hosts might go down or move. Thus, the association of a MAC address to a port number is valid only within a given period of time.

Token Ring Switches

Token ring switches are used to interconnect token ring LANs. Each port in a token ring switch supports either 4 Mbps or 16 Mbps ring speeds, which are configurable through the system software. Ports can be configured to one or multiple logical ring groups. Figure 9 illustrates the configuration of one token ring switch and one Ethernet switch connecting two LANs.

A token ring switch can perform switching in one of three modes. In the first mode, *transparent switching*, the switch uses the backward learning technique to learn which ring can be accessed through which port. This learned information is used to determine how to forward frames. If an arriving frame is destined for a MAC address that has not yet been learned by the switch, then the frame is flooded to all ports belonging to the same group on the switch, excluding the port that received the frame.

Figure 8: A switched Ethernet LAN

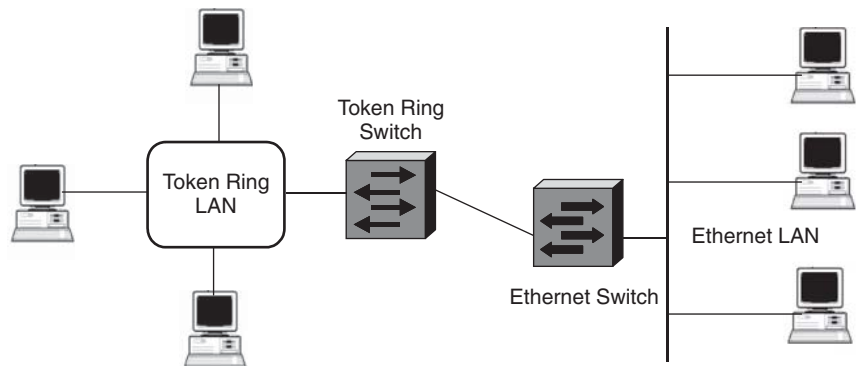

Figure 9: The configuration of a token ring switch and an Ethernet switch

The second mode is *source-route transparent switching*, which combines source-route bridging and transparent bridging. Under this mode, a switch makes forwarding decisions based on the data in the *routing information field* (RIF), if present. The RIF details each interface and path through which the traffic is flowing. If a frame does not contain a RIF, then the switch will perform transparent switching.

The third mode is source-route switching. Under this mode, the source host needs to determine the path to reach the destination host. The path is represented by route descriptors carried in frames. Intermediate switches forward the frames based on these descriptors. Source-route switching has become popular for switches that offer *microsegmentation*, a feature that allows multiple switch ports to be given the same logical ring number so that frames are switched either by destination MAC address on the logical ring segment or by the route descriptors carried in source-routed frames (Puzmanova 2002).

VLAN Switching Capability

A LAN built and designed only with traditional LAN switches, such as Ethernet switches and token ring switches, appears as a flat network topology consisting of a single broadcast domain. A *virtual LAN* (VLAN) is a logical grouping of hosts that appear to one another as if they are on the same physical LAN segment even though they spread across multiple LAN segments. Only the hosts that are in the same VLAN belong to the same broadcast

domain. This allows a network administrator to logically segment a LAN into different broadcast domains. VLANs provide several advantages, including increasing the flexibility, reducing the network load, and ensuring security. Figure 10 shows two VLAN switches connecting seven hosts into three VLANs.

In Figure 10, the hosts that are equipped with VLAN-capable Ethernet interfaces can generate or receive 802.1Q frames directly to or from the switch. In case a host belongs to multiple VLANs, it creates virtual interfaces (cloned interfaces) for each VLAN to which the host belongs. The two LAN switches are configured to understand VLAN memberships and 802.1Q frames. The VLAN memberships specify which hosts belong to which VLAN. Therefore, a VLAN switch maintains two tables: a membership table and a forwarding table. The forwarding table can be built using the backward learning technique discussed earlier. The membership table must be configured by the system administrator. The following methods are used (Tanenbaum 2003):

- Every port is assigned a VLAN identifier.
- Every MAC address is assigned a VLAN identifier.
- Every layer 3 protocol or IP address is assigned a VLAN identifier.

Figure 11 shows the frame formats of 802.3 and 802.1Q. It can be seen that the only change in 802.1Q is the addition of a pair of two-byte fields. The first one is the VLAN protocol ID, which has the value of 0×8100 . The second

Figure 10: Two VLAN switches connect seven hosts into three VLANs

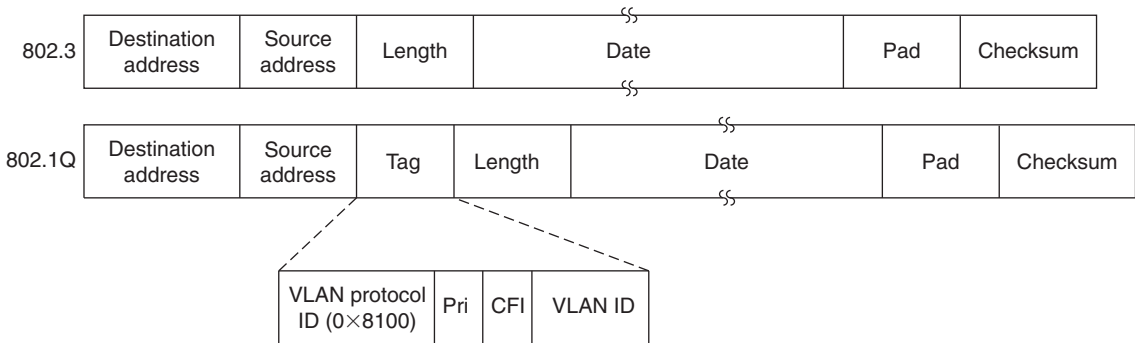

Figure 11: The 802.3 (legacy) and 802.1Q Ethernet frame formats (Tanenbaum 2003)

field contains three subfields: a twelve-bit VLAN identifier, a one-bit flag denoting whether MAC addresses in the frame are in canonical format, and a three-bit field indicating the priority of the frame. When a VLAN frame arrives at a VLAN-aware switch, the switch uses the VLAN identifier as an index in a forwarding table to find out which ports to send it on.

Spanning Tree Algorithm

To increase reliability, two or more switches are used in parallel between pairs of LANs. This deployment, however, also creates loops in the network topology. When loops occur, some switches see stations appear on both sides of the switch. This condition confuses the forwarding algorithm and allows duplicate frames to be forwarded. To provide both path redundancy and loop-free topology, the *spanning tree algorithm* (Perlman 1999) defines a tree in which some switches, ports on switches, or both are active and others are blocked. The blocked switches or ports constitute the disconnected portions of the original topology, thus creating the tree topology. Note that a blocked switch does not participate in frame forwarding, but it does listen to all transmissions, monitoring all activity and ensuring the health of other nonblocked switches. If one network segment becomes unreachable, the spanning

tree algorithm reconfigures the tree topology and reestablishes the link by activating the blocked path.

The basic idea behind the spanning tree algorithm is that switches transmit special messages called *bridge protocol data units* (BPDUs) to calculate a spanning tree. Each BPDU contains the following minimal information:

- the identifier of the current root switch,
- the cost of the path to the root from the transmitting port,
- the identifier of the switch that sends the BPDU, and
- the identifier of the transmitting port.

The switch's identifier, called the *switch ID*, is eight bytes long and contains a switch priority (two bytes) and the lowest MAC address (six bytes) among the switch's MAC addresses. Each port ID is sixteen bits long with two parts: a six-bit priority setting and a ten-bit port number. If all switches are enabled with default settings, then the switch with the lowest ID in the network is elected the root of the spanning tree and is henceforth referred to as the *root switch*. However, because of traffic patterns, the number of forwarding ports, or line types, this switch might not be the ideal root switch. The ideal switch can

become the root switch by increasing its priority (lowering the numerical priority number).

The exchange of BPDUs results in the following:

- One switch is elected as the root switch.
- The minimum-cost path to the root switch is calculated for each switch.
- A designated switch for each LAN segment is selected. This is the switch closest to the root switch through which frames will be forwarded to the root switch.
- A root port for each switch is selected. This is the port that provides the best path from the switch to the root switch.
- Ports included in the spanning tree algorithm are selected.

To monitor the *health* of the spanning tree, the root switch periodically broadcasts a *hello BPDU* on its branches. The reception of this broadcast hello BPDU by switches at the next level on the tree in turn triggers a transmission of a HELLO BPDU along their branches. This continues down the tree until it reaches the leaf switch, which transmits a hello BPDU on its local LAN segments primarily for the benefit of any blocked switches that might be attached at that level to signal its continued health. If at any point a switch in the tree does not send a hello BPDU within a specified interval of time, the neighboring switches (including blocked ones) will sound the alarm by initiating a new round for creating a spanning tree. In the event that the root switch begins to fail or have network problems, the spanning tree algorithm allows the other switches to immediately reconfigure the network with another switch acting as the root switch.

WAN SWITCHES

WAN communications occur between geographically separated sites connected by one or more subnets. In most WANs, the subnet consists of two distinct components: WAN links and WAN switches. The *WAN links* are the transmission media to move packets between hosts. The *WAN switches* are the devices that connect WAN links. They are designed to efficiently share both public and private WAN facilities among multiple users. WAN switches differ in many aspects such as switching technology and switching capability. However, all of them offer two fundamental functionalities: packet queuing and packet switching. This chapter concentrates on packet queuing. Information about packet switching can be found in Chapter 68.

Packet queuing means that when multiple packets want to access the same resource, only one of them can get access. The others must be temporarily stored in the buffers that are most often organized in logical queues. According to the location of the buffers, there are five different queuing schemes: input queuing, output queuing, shared-memory queuing, virtual output queuing, and combined input-and-output queuing. In *input queuing* switches, packets are first stored in the buffers located on the input port before they are scheduled to access the switch fabric. If more than one packet is destined for the same

output port, then only one packet is switched. Others are temporarily stored at the input buffer. An input queuing switch has the advantage that the operation speed of the switch fabric needs to be only slightly higher than the external link speed, which makes the implementation easier. However, the switch throughput is limited to 58.6 percent because of the well-known *head of line* (HOL) blocking phenomenon (Karol, Hluchyj, and Morgan 1987). Moreover, it is hard to provide delay guarantees in input queuing switches.

In *output queuing* switches, incoming packets are immediately switched from the input port to the output port and stored in the buffers located on the output port. Output queuing switches have the best possible performance for all traffic distributions, especially for those applications in which traffic behavior is difficult to predict. To implement the output queuing, however, the switch fabric needs to operate N times faster than the external links. This is because all N arriving packets may be destined for the same output port in the same cycle, so the fabric may become a bottleneck. The shared memory queuing technique has been illustrated in Figure 2. As we already learned, the main problem for this type of switch is that the memory and the central control unit must run at least N times faster than the link speed. This makes shared-memory queuing less attractive for large high-speed switches.

In *virtual output queuing* switches, buffers are allocated on the input port card. To completely overcome the HOL blocking, each input port organizes the buffer to N logical queues, each associated with an output port. A packet scheduler chooses up to N packets from the total N^2 logical queues to transmit to N output ports and thus achieves a 100 percent throughput. The nice feature of the virtual output queuing technique is that the operation speed of the switch fabric needs to be only slightly higher than the external link speed. To further improve the switching capability and accommodate diverse link speeds, buffers are also allocated at the output ports. This queuing technique, depicted in Figure 12, is called *combined input-and-output queuing* (McKeown, Prabhakar, and Zhu 1999).

Three primary WAN switches are widely used in today's networks: packet switches, ATM switches, and circuit switches. This chapter concentrates on the first two types. Next we introduce the specific designs and features of two types of WAN switches. For clarity, we will use the term *packet* to represent the protocol data unit when introducing packet switches and use the term *cell* when introducing ATM switches.

Packet Switches

Packet switches are one of the primary devices that form the backbone of the WAN. Unlike the traditional LAN switches that operate at layer 2, packet switches make switching decisions based on layer 3 information—that is, on IP addresses. Because of this, packet switches are similar to the well-known network layer device, the *router*. They both use IP addresses to make the forwarding decision and both offer layer 3 features such as security management, flow control, and IP fragmentation. The primary difference between them is that WAN switches do not perform the *routing process*, which is actually the

Figure 12: The architecture of a 4×4 combined input-and-output queuing switch

main task of routers. Figure 13 illustrates three packet switches within a packet-switched WAN.

Other important services and features supported by most packet switches are (Puzmanova, 2002):

- automatic line quality monitoring,
- end-to-end error control,
- network monitoring,
- restricted and multiple addressing options,
- hunt group facilities,
- priority and preemption facilities, and
- fast select to minimize call-processing overhead.

ATM Switches

ATM switches are the primary devices in ATM networks. They are frequently used to construct a high-speed backbone for WANs. The design of ATM switches is based on the *cell-switching* technique in which every packet is broken into equal-sized cells at the input port. More information about cell switching can be found in Chapter 72. Figure 14 illustrates ATM switches within a cell-switched WAN.

Most ATM switches support the following important services and special features:

- set up and maintain the end-to-end connections;
- perform the *virtual path identifier* (VPI) and *virtual circuit identifier* (VCI) table lookup to decide the outgoing cell's VPI and VCI;
- provide feedback information from the output port to the input port;
- resequence cells to the order in which they came into the input port in case cells are out of order;
- perform congestion control; and
- decide which cells should be discarded if needed (for bursty data connections, it is better to discard the entire frame rather than a few cells from each of many frames).

ATM switches can also be used to construct a LAN. In doing so, a LAN emulation technique is needed so that the traditional applications do not need to make any changes.

Multicast Switching Capability

Traditionally, the design of packet switches is optimized for supporting unicast traffic. As the fraction of multicast traffic on the Internet is continuously growing, the ability to efficiently support both unicast and multicast traffic becomes increasingly important. The design challenge of multicast switches stems from the nature of multicast packets—that is, a multicast packet has multiple destinations. The number of destinations for a multicast packet is termed *fanout*. In unicast switches, once a packet is transmitted to the destined output port, the packet can be removed from the buffer. However, in multicast switches, a packet can only be removed from the buffer if all of its destinations have received a copy of the packet. Simply considering multicast as a special case of unicast does not allow the architecture to be scalable. In this section, we introduce the architecture of multicast switches by addressing two specific issues: packet replication and multicast queuing.

Packet Replication

The *packet-replication* procedure in a multicast switch can be performed either with or without a copy network. With a dedicated copy network, multicast packets are first replicated in the copy network and then forwarded to distribution networks and routing networks (Chao et al. 1997). Without a dedicated copy network, the packet replication can be performed in three ways.

First, to perform the replication at the input side, a multicast packet with a fanout of f is copied to f queues based on its destinations. Then each copy is handled exactly the same as a unicast packet. This works only if the

multicast traffic is a small fraction of the total traffic and the switch fabric operates faster than the external links.

Second, to perform the replication inside the switch fabric, one approach is to take advantage of the nice feature of shared-memory switches—that is, good support of multicast traffic (Francini and Chiussi 2002). Another approach is to use parallel crossbar-based fabrics as shown in Figure 15 (Iyer and McKeown 2001 “Making”).

Third, the packet-replication process can also be performed at the output side of the switch as shown in Figure 16 (Chao and Choe 1995).

Among these approaches, it appears that the parallel crossbar-based fabrics approach is the most attractive

Figure 15: A 2×2 multicast switch based on parallel crossbar-based fabrics

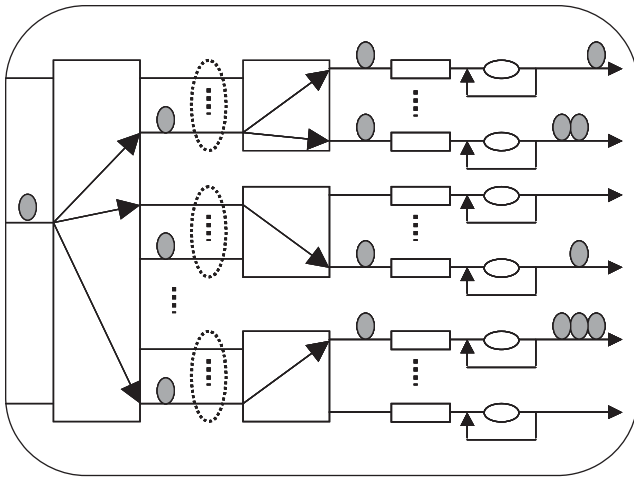

Figure 16: A switch performing multicasting at the output side

because of the following reasons. First, it is possible that multiple copies of the same multicast packet can be forwarded to different output ports during the same cycle. Provided that only one packet is transferred to each output at each cycle, the cost of transferring one multicast packet equals the cost of transferring one unicast packet. Second, multiple bus transactions can occur simultaneously, which means that the fabric will not be a potential bottleneck.

Multicast Queuing

Multicast queuing is entirely different from unicast queuing. For unicast, it is commonly believed that *virtual output queuing* (VOQ) is the best queuing scheme in terms of achieving a high switch throughput. To achieve the same performance for multicast switches, $2^N - 1$ queues are needed at each input port, which makes it impractical for large-scale switches. One simple multicast queuing scheme is to allocate a single *first-in, first-out queue* at each input port for multicast traffic (Hui and Renner 1994). Although this scheme can be easily implemented because of its simplicity, the HOL blocking significantly limits the switch throughput and the link utilization.

To overcome the HOL blocking, window-based queuing was introduced such that packets other than the HOL packet are allowed to be transmitted before the HOL packet during the current cycle (Chen et al. 2000). The increased scheduling space results in a better throughput. The price paid for this is that a reordering circuit is needed at each output port and the input queues must have the random access capability. Another design to alleviate the HOL blocking is to allocate multiple multicast queues at each input port (Bianco et al. 2003; Song et al. 2005). Because more queues provide more scheduling spaces, the throughput can be increased significantly.

NEW DEVELOPMENT

No Speedup Requirement Architectures

As we pointed out earlier, although output queuing switches have the best possible performance for all traffic

distributions, the switch fabric needs to operate N times faster than the external links. Thus, the switch fabric may become a bottleneck. The combined input-and-output queued switch architecture shown in Figure 12 can potentially achieve the performance comparable to that of an output-queued switch if the switch fabric operates two times faster than the external links (Krishna et al. 1998). However, the speedup requirement of switch fabric needs memories with shortened access time and requires a scheduler to make scheduling decisions within reduced time, which is quite difficult even for a speedup of two. Two new switch architectures that require no speedup have been recently proposed: *parallel switching architecture* (Iyer and McKeown 2001 “Making”) and *multiple input/output-queued* (MIOQ) switch architecture (Lee and Seo 2006).

The parallel switching architecture is composed of input demultiplexers, output multiplexers, and parallel switches. An incoming stream of packets is spread packet by packet by a demultiplexer across the parallel switches and then recombined by a multiplexer at each output port. For an $N \times N$ MIOQ switch, the architecture is composed of N input buffers at each input port, M output buffers at each output port, k parallel crossbar switches, and a scheduler. As shown in Figure 17, each parallel switch is connected with each input via an ingress line and connected with each output via an egress line. Therefore, with k parallel crossbars, each input sends up to k packets to k ingress lines and each output receives up to k packets from k egress lines. However, because no speedup of any component is assumed, only one packet from each input buffer can be selected and transmitted via one k parallel switch.

Mixed Traffic Switching Capability

Traditionally, the design of packet switches is optimized for supporting unicast traffic. As the fraction of multicast traffic on the Internet continuously grows, the ability to efficiently support mixed unicast and multicast traffic becomes increasingly important. Two central challenges are how to avoid HOL blocking and how to buffer unicast and multicast packets. One design is to maintain N virtual output queues for unicast traffic and one multicast queue for multicast traffic (McKeown et al. 1997; Andrews, Khanna, and Kumaran 1999). Although this queuing policy can be easily implemented because of its simplicity, multicast HOL blocking significantly limits the switch throughput. Another design to alleviate multicast HOL blocking is to assign a multicast packet into one of the virtual output queues that correspond to one of the packet’s destinations (Francini and Chiussi 2002; Minkenberg 2000). But because multicast traffic is mixed together with unicast traffic, the overall packet delay is compromised considerably. To efficiently support both unicast and multicast traffic, new switch architecture was recently proposed as shown in Figure 18 (Zhu and Song 2006).

In this architecture, each input port maintains N unicast queues based on virtual output queuing technique and M ($M < N$) multicast queues based on a load-balancing policy. Both theoretical analysis and simulation studies suggest that this architecture exhibits a promising

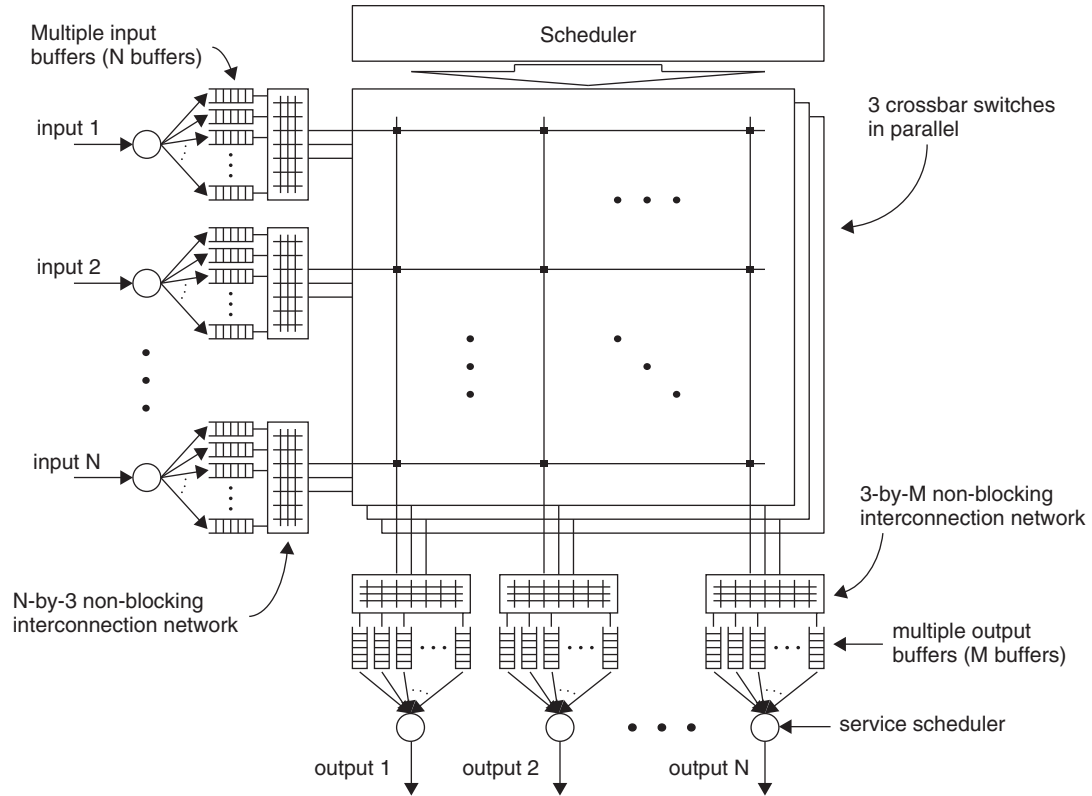

Figure 17: An $N \times N$ MIOQ switch architecture with three crossbar switches in parallel (Lee & Seo, 2006)

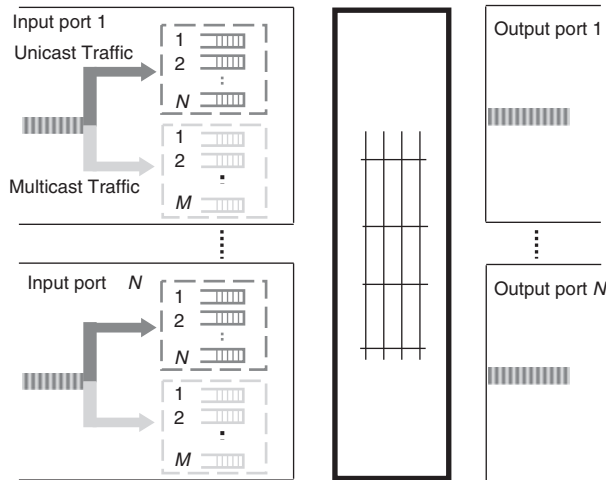

Figure 18: An $N \times N$ switch supporting both unicast and multicast traffic (Zhu & Song, 2006)

performance in terms of throughput, delay, and packet loss ratio.

CONCLUSION

We have introduced the architecture of LAN switches and WAN switches. For each type of switch, we presented the main hardware components and their functionalities, the switching modes, the main design issues, and the

main services and features. For LAN switches, we have studied the VLAN switching capability and the spanning tree algorithm. For WAN switches, we have addressed the design challenges of multicast switches. Specifically, we presented the techniques of multicast packet replication and multicast queuing. New development in packet switches design was also discussed. We concluded that the fundamental functionalities of switches are interconnecting networking devices and forwarding frames. Four metrics have been defined to measure switch performance. Factors that affect switch performance and the technologies that improve switch performance were also discussed.

The architectures of contemporary switches are continuously evolving. We anticipate that future switches will provide better end-to-end quality of service guarantees for each application, ensure reliable and secure services, and continuously reduce design complexity and cost.

GLOSSARY

Asynchronous transfer mode (ATM): A high-speed multiplexing and switching method utilizing fixed-length cells of fifty-three octets to support multiple types of traffic.

Header error control (HEC): A field in a packet or cell header that contains information to detect and correct errors in the cell header.

Head of line (HOL) blocking: A phenomenon in which a blocked HOL packet prevents the packets behind it from receiving service. This happens because only the HOL packets can be transmitted.

Local area network (LAN): A data communications system that lies within a limited spatial area, has a specific user group, has a specific topology, and is not a public switched telecommunications network but may be connected to one.

Medium access control (MAC): A sublayer of the data-link layer that controls how the shared medium—for example, an Ethernet cable—is accessed by the machines attached to the medium.

Switch: A networking device that operates at data-link layer, forwards frames, and interconnects LANs.

Switching fabric (SF): Combination of hardware and software that moves data from input ports to output ports.

Virtual channel identifier (VCI): A sixteen-bit field in an ATM cell's header that identifies the cell's next destination as it travels through an ATM network.

Virtual LAN (VLAN): A network of computers that behaves as if the computers are connected to the same wire even though they may be physically located on different segments of a LAN.

Virtual output queuing (VOQ): A queuing mechanism in which each input port organizes the buffer to N logical queues, each associated with an output port.

Virtual path identifier (VPI): An eight-bit field in an ATM cell's header that identifies the virtual path (a bundle of virtual channels that have the same end point) to which the cell belongs as it travels through an ATM network.

Wide area network (WAN): A physical network that provides data communications to a larger number of independent users than are usually served by a LAN and is spread over a larger geographic area than that of a LAN.

INTRODUCTION

A LAN segment is usually restricted to span a small geographical area and may only support a small number of hosts (Forouzan 2002). Adding more hosts can cause the performance of the LAN segment to degrade. Furthermore, if the geographical span of the LAN segment is increased, end stations may no longer be able to communicate. However, LAN segments can be joined together, without an appreciable performance degradation, by means of a bridge (Wikipedia 2007). Using many bridges, a conglomerate of LAN segments—an *extended LAN*—can be created that may cover a reasonably large geographical area, typically a campus, supporting a larger number of end stations. The term *LAN* is used in the literature to refer to either a LAN segment or an extended LAN.

The end stations (or *hosts*, as they are sometimes called) are connected to a *local area network* (LAN) using one of many LAN technologies, several of which have been standardized by the 802 committee of the Institute of Electrical and Electronic Engineers (IEEE). The most commonly used LAN technology is based on the *carrier sense multiple access with collision detection* (CSMA/CD) protocol and was standardized by the IEEE 802.3 subcommittee. Another LAN standard based on CSMA/CD is Ethernet (also referred to as Ethernet II or DIX Ethernet as standardized by Digital Equipment Corporation, Intel, and Xerox), and it is quite similar to the one standardized by the IEEE 802.3 subcommittee (Firewall 2007). In fact, the CSMA/CD-based LANs in use today are those that have been standardized by IEEE 802.3 and are backward-compatible with Ethernet; both are usually referred to as *Ethernet*. Therefore, we will also use the terms 802.3 LAN and Ethernet LAN interchangeably, unless we need to highlight the differences between the two. Because CSMA/CD-based LANs are the most prevalent these days (Tanenbaum 2002), these will be our primary focus in this chapter and any reference to a LAN will implicitly mean an 802.3 or an Ethernet LAN.

The Ethernet standardization included two layers of the networking stack: the physical layer and the data link

Table 1: Tasks of Various IEEE 802 Subcommittees

Subcommittee	Assigned/Accomplished Tasks
802.1	Common issues
802.2	Logical link control (LLC)
802.3	CSMA/CD-based LANs
802.4	Token bus LAN
802.5	Token ring LAN

layer. Because bridges are meant to connect various LAN segments, they also implement the physical and data link layers of the networking stack. The data link layer of the networking stack is subdivided into the *media access control* (MAC) sublayer, which depends on the actual physical technology (e.g., Ethernet or token ring); and the *logical link control* (LLC) sublayer, which is independent of the physical technology used to implement the LAN and allows sharing of the data link resources by providing a unified interface that supports a common set of services (Forouzan 2003). A brief description of tasks accomplished by some relevant subcommittees of the IEEE 802 committee is given in Table 1, and Figure 1 shows a picture of the networking stack standardized by this committee.

A LAN segment uses a physical medium that is shared by all of the end stations connected to that segment. In other words, the physical medium is of a broadcast type, and the end stations or hosts contend with one another to transmit a chunk of data, referred to as a *frame*, on the LAN segment. All such stations are said to be in the same collision domain. If two stations transmit at the same time, then a collision happens and a back-off mechanism is used by the hosts to retry the transmission of the frame (Keiser 2001).

Sometimes, either a hub or a repeater is used to connect many LAN segments together. Many such devices use store-and-forward technology; others may forward

Figure 1: Networking stack showing the layers standardized by the IEEE 802 committee

the frame as it is being received. In the former case, each LAN segment has its own independent collision domain; whereas in the latter case, LAN segments connected through the device are part of the same collision domain. In either case, both LAN segments belong to the same broadcast domain; although the use of a hub or repeater has extended the range and increased the capacity, an *extended* LAN has not been formed. Unfortunately, distinguishing a hub from a repeater has become quite difficult these days with the proliferation of devices that enjoin LAN segments. We will not attempt to differentiate between these devices, especially because most devices available these days use store-and-forward technology. A bridge also enjoins LAN segments and uses store-and-forward technology and may well be confused with a hub or a repeater, but we will clearly differentiate a bridge from other LAN devices as a LAN device that can run the spanning tree algorithm. Most bridges also learn end station addresses and perform selective forwarding based on such learning.

The terms *MAC bridge*, *Ethernet bridge*, *LAN switch*, and *Ethernet switch* all refer to a bridge. Note, however, that a *switch* is a generic term and may sometimes refer to devices other than bridges (Perlman 2000). The term *LAN segment* may refer to a single LAN segment or different segments connected through a hub or repeater within the same collision or broadcast domain. An extended LAN is a topology of many LAN segments that are connected using one or more bridges.

Every broadcast medium must use a mechanism to identify the sender and the receiver. On CSMA/CD-based LANs, a *LAN address* (also known as *MAC address*, *Ethernet address*, *hardware address*, or *physical address*) is used to identify the sender and the intended receiver (Stallings 2006). Every Ethernet frame contains a source LAN address and a destination LAN address. IEEE has standardized 48-bit addresses for use with IEEE 802.3 LANs. LAN addresses are globally unique and are *burned* into a LAN card by the manufacturer. The first three octets of each 48-bit LAN address represent the *vendor code*, also referred to as the *organizationally unique identifier* (OUI), and indicate a block of 2^{24} LAN addresses. A vendor, who may purchase one or more blocks of LAN addresses, assigns the last three octets of a block to uniquely identify the complete 48-bit address. Note that a single vendor may buy address blocks, each of which has different OUIs. An example Ethernet address using a well-accepted representation is 00:0F:1F:B2:0E:CC, where 000F1F represents the manufacturer (Dell), and the remaining portion is selected by the manufacturer uniquely for each card.

The sending host includes the source and destination LAN addresses within each frame. The last bit of the first octet of the destination LAN address is the first bit

that is sent on the physical medium. A 0 value of this bit means that the desired destination is a single host, while a 1 in this bit position designates a multicast destination address, indicating that this frame is intended for multiple hosts. Because of the broadcast nature of the LAN, every connected station receives every frame transmitted in the same broadcast domain and immediately examines the destination address. If the destination address is a unicast LAN address different from the receiving station's address, then the frame is discarded (otherwise, it is processed further). Bridges, on the other hand, must process all of the frames received at all of their ports, a *port* being a physical point connecting a bridge to a LAN. We refer to this mode of listening, where a bridge listens to (and processes) every frame, as *promiscuous listening*. For efficiency reasons, end hosts do not usually listen promiscuously, but bridges must listen promiscuously because they are meant to forward frames from one segment to other segments.

TRANSPARENT BRIDGES

Bridges can be broadly classified as either *transparent* or *source-routing*. Bridges are transparent in the sense that two stations on two different segments of an extended LAN, formed by using transparent bridges, communicate as if they are on the same LAN segment. In other words, end stations and other bridges are unaware of the presence of a transparent bridge in the network. On the other hand, source-routing bridges explicitly forward frames to other source-routing bridges in the network by specifying a path included within the frames. In this chapter, we will only consider transparent bridges because those are the ones commonly used in practice. Figure 2 shows several end stations connected to a LAN segment, whereas Figure 3 indicates the same end stations divided onto two LAN segments connected through a bridge. If the bridge is transparent, the end stations will not notice any difference in topology in the two cases.

The two obvious benefits of bridges are an increased number of supported end stations and an extension in the geographical range over which a LAN can be used. A third, not so obvious, benefit is the potential for increased transmission rate per LAN segment. This benefit stems from

Figure 2: Stations connected to a LAN segment

Figure 3: A bridge connecting two LAN segments

Figure 4: A transparent bridge with smart forwarding

the fact that bridges may forward frames *smartly* such that a frame is not blindly forwarded to every LAN segment as is done by other store-and-forward LAN devices (such as repeaters and hubs). Instead, a bridge forwards the traffic only to those LAN segments where necessary. This limits the traffic on a given LAN segment, resulting in the possibility of accommodating more traffic per segment. To illustrate this benefit, consider a LAN segment with an average traffic of R packets per second. If we divide the stations on this LAN segment into two groups, one on each LAN segment, on either side of a smart bridge as shown in Figure 4, then the average traffic on each segment will be $R/2$ packets per second. On average, half of the traffic generated on each segment is directed for the same segment while the other half is destined for the other segment. Thus, the average traffic on each segment is $3R/4$, and it must not exceed the throughput capacity, C , of the segment—that is, $3R/4 < C$, which means that the effective transmission rate may exceed C up to a value $4C/3$ and is in contrast with the case when a single segment was used and the effective transmission rate was limited to the value C .

The increase in effective transmission rate depends not only on the number of segments and bridges used to make an extended LAN topology but also on the configuration in which the segments and bridges are connected. Note that the increase in transmission rate is possible because we assume that the bridges do not unnecessarily forward frames to all segments; such is not the case with other LAN devices that do not perform any learning, whether or not they use a store-and-forward mechanism.

BRIDGE OPERATION

From earlier discussion, we learned that the end stations or hosts are connected to LAN segments, and LAN segments are connected to one another by means of bridges to form an extended LAN or simply a LAN. We may use a router to connect two LAN segments, but this results in the two segments belonging to two different broadcast domains. In such a case, end hosts on different segments will need to communicate using a different mechanism compared to what would be used if they were on the same segment (Matthews 2005; Olifer and Olifer 2006).

Transparent bridges listen to every frame promiscuously on each physical interface (port) and either filter (i.e., do not forward) or store and forward the frame to some of the other ports based on a local database called *filtering database* or *forwarding database* (FDB). The

entries in an FDB indicate the port (or ports) where a frame for a given destination should be forwarded. To populate the forwarding database, for every received frame, the source LAN address is stored together with the port on which the frame is received. This is indicative of the fact that the transmitting end station is approachable through that particular port. The forwarding database is created in a memory area called the *station cache*. Sometimes, the terms *forwarding database* and *station cache* are used interchangeably. It is likely that a station might move from one place to another, necessitating that the FDB entries be refreshed periodically.

For each received frame, the bridge examines the destination LAN address; if it is found to be a unicast address, then the forwarding database is searched for the destination LAN address in the frame. If the destination LAN address is not found in the FDB, then the frame is forwarded to all of the ports except for the one on which it is received. However, if an entry for the destination LAN address is found in the FDB, the frame is forwarded to the corresponding port in that FDB entry. The frame is not forwarded at all if the port number in the FDB is the same as the one on which the frame is received, a situation that arises when the source and destination stations reside on the same LAN segment.

Learning and Forwarding Operation

To illustrate the learning and forwarding mechanism, consider the topology shown in Figure 5, adapted from Perlman (2000).

Suppose that the first frame transmitted in this topology is directed from P to L. To begin with, we assume that the station cache is empty. The bridge forwards the frame to ports 2 and 3 and makes an entry in the FDB that station P is approachable through port 1. Next assume that M transmits a frame destined for P. Because the station cache now includes the station P, the frame is only forwarded to port 1. If the next frame is transmitted from station Q with P as the destination, the frame is not forwarded at all on any of the ports because the bridge determines that the source and the destination both reside on the same LAN segment. Note that the broadcast nature

Figure 5: Learning and forwarding in a transparent bridge

of the LAN segment ensures that station P would have received this frame directly. Finally, if station R transmits a frame with S as the destination, the frame is forwarded to ports 1 and 3 because there is no entry for station S in the FDB at that time.

The same learning and forwarding mechanism as described above is independently used at each bridge in the extended LAN. In fact, just as the end stations do not notice the presence of transparent bridges in an extended LAN, other bridges also remain unaware of the presence of transparent bridges in an extended LAN topology. Each bridge builds its own FDB based on the frames received at each port (or through manual intervention by the network administrator) and forwards or filters frames according to the FDB entries, irrespective of the FDB entries of other bridges.

Loop-Free Operation

It is clear from the bridge operation described in the previous section that a bridge may make copies of a frame received at one of its ports for further transmission to some of its other ports. This means that an extended LAN topology with loops is prone to the proliferation of frames, and frames may run in loops forever. Furthermore, the presence of loops may also cause the learning process to become unstable. Thus, it appears that loops in extended LANs should be avoided at all cost. However, loops may provide path redundancy when a portion of the extended LAN fails and, therefore, enforcing a loop-free topology by careful deployment of network resources (bridges and LAN segments) is not necessarily desirable. Instead, bridges in the topology may be designed to run a distributed protocol that logically prunes part of the topology in order to avoid loops. This pruning is obtained by blocking some ports of bridges and is temporary in the sense that the blocked ports may be unblocked if some portion of the network fails.

In the normal operation of bridges, some ports remain part of the extended LAN such that data frames are received from and transmitted to these ports while some ports are blocked for data frames. Here we differentiate between *data frames*, which are generated by the end stations; and *control frames*, which are generated by bridges and communicated to other bridges to ensure proper working through a distributed protocol. This protocol reduces the original topology into a spanning tree which, by definition, connects all nodes (i.e., bridges) in a loop-free manner. Although data frames are not allowed across blocked ports, bridges may receive control frames on such ports.

The distributed protocol must use an algorithm to automatically reconfigure an arbitrary topology into a loop-free topology in a short bounded time without significant overhead (i.e., without transmitting too many control frames). The reduced topology is loop-free and is obtained by eliminating the blocked ports from the complete original topology. We call this reduced topology an *active topology*, which necessarily is a spanning tree. A popular algorithm for finding the active topology, originally designed by Radia Perlman, is called the *spanning tree algorithm* (STA), and it implicitly includes the protocol

for exchanging control frames between the bridges. Sometimes, the STA is also referred to as the *spanning tree protocol* (STP); we will use both STA and STP interchangeably. Newer versions of STA have also been proposed and are used in practice. The STA is the key ingredient of bridge operation and is given in detail in the following section. Subsequent sections will cover applications and variations of this algorithm.

SPANNING TREE ALGORITHM

In an extended LAN (also known as a *switched Ethernet*), each bridge (or Ethernet switch or layer 2 switch) runs a distributed protocol, the *spanning tree protocol* (STP) (which is sometimes referred to as the *spanning tree algorithm*, or STA) to facilitate the formation of a spanning tree of the extended LAN (IEEE Standards Committee 2004). The resulting spanning tree is used by the bridges to forward (or filter) the frames from one LAN segment to another.

The spanning tree is formed when bridges exchange control information among themselves. This step does not require that any end station be attached to any of the LAN segments; the (address) learning process, on the other hand, requires that end stations are attached to LAN segments. Furthermore, learning is solely based on the information originated by the end stations and is not dependent on the information originated by bridges.

Description

The terms *spanning tree algorithm* and *spanning tree protocol* are usually used interchangeably (and we will also use them as such here), but there is a clear difference between the two. An implementation of the STA runs on each bridge in the extended LAN, while the STP is used to exchange information among bridges to create a spanning tree in order to eliminate loops that may exist in the topology. Thus, STA and STP both support each other during the formation of a spanning tree. As already mentioned, a spanning tree is needed in a topology of LAN segments connected by bridges because loops in the network topology create instability in learning besides the endless circulation of multicast and broadcast traffic.

The spanning tree is created by an exchange of special messages between bridges called *configuration bridge protocol data units*, or *configuration BPDUs*. We will use the term *BPDUs* to refer to *configuration BPDUs* throughout this chapter. In the spanning tree protocol, bridges exchange and process the BPDUs. Toward this end, one bridge is selected to be the root of the spanning tree. The spanning tree thus created consists of shortest paths from each bridge to the root.

To explain the spanning tree algorithm and protocol, we assume that the BPDU message has the following form:

```
<Root ID>.<Cost>.<Transmitting Bridge ID>.  
                                <Transmitting Port ID>
```

Thus, a BPDU contains all of the information given in Table 2.

Table 2: Information Contained in BPDUs

Data	Explanation of Data
Root ID	ID of the bridge currently believed to be or known to be the root
Transmitting bridge ID	ID of the bridge transmitting this BPDUs
Cost	Cost of the least cost path from the transmitting bridge to the currently known root
Transmitting port ID	ID of the port that transmits the BPDUs

Protocol Operation

As described above, the protocol serves to build a tree in which one bridge is determined to be the root, while the other bridges make up a spanning tree. Bridges can only forward data frames toward or away from the root bridge.

Each bridge is assigned a unique bridge ID, typically by an administrator based on the Ethernet addresses of its ports, and the root bridge is determined to be the one with the lowest bridge ID (LinuxNet 2007). When a bridge first boots up, it has no information about other bridges on the LAN, so it believes that it is the root bridge itself. Therefore, it builds a BPDUs of the form `<its bridge ID>.<0>.<its bridge ID>.<Port ID>` and transmits this BPDUs on each of its ports. A BPDUs transmitted by a bridge on a given port is multicast to all of the bridges on the LAN segment to which it is connected via that port. Likewise, a bridge receives BPDUs sent by all of the other bridges on that segment. The bridge must process the received information and reevaluate which bridge it now believes to be the root bridge and the distance to the new root bridge. Depending on the BPDUs received, the bridge may *block* some of its ports and *designate* others. Finally, the bridge sends out this newly determined information on all designated ports. The process of sending, receiving,

and processing BPDUs continues until a stable spanning tree is formed. After the algorithm converges, one bridge has been elected as the root bridge, while all other bridges have calculated their shortest path cost to the root bridge. An example of a spanning tree in a given topology is shown in Figure 6.

The bridge with bridge ID 20 (or simply bridge 20) is determined to be the root bridge because it has the lowest bridge ID. Thus, all of its ports are designated. Every other bridge has found its root port and either designated or blocked all other ports. A root port is the port that leads to the root bridge along the shortest path, and a designated port is an unblocked port connected to a segment. A blocked port is not part of the spanning tree, and no data traffic flows through it.

In Figure 6, bridge 50 has two ports that lead to the root bridge with the same cost. In this case, the transmitting port ID of bridge 20 is used to determine that port 1 of bridge 50 should be the root port (details shortly).

There can only be one designated bridge per LAN segment, and it is the bridge with the lowest cost to the root. Thus, the root bridge is designated on all of the LAN segments to which it is connected, and all ports of the root bridge are designated. In case of a tie in determining the designated bridge for a LAN segment, the bridge with the lowest bridge ID is chosen. Thus, for segment 3, bridge 57 (rather than bridge 78) is chosen as the designated bridge.

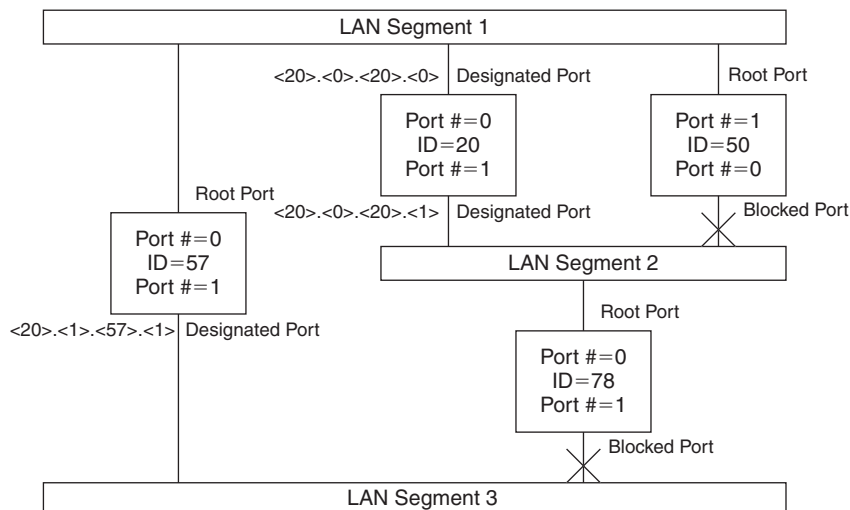

Protocol Algorithm

The protocol algorithm is described below (Cisco 1997).

- Initially, each bridge assumes itself to be the root bridge and transmits the following BPDUs on each of its ports:

`<Transmitting Bridge ID>.<0>.<Transmitting Bridge ID>.<Transmitting Port ID>`

- During a period of time (called a *cycle*, which can be arbitrarily short), each bridge receives BPDUs on each of its ports. For each port, the bridge saves the “best” among all of the BPDUs received and determines the

**Figure 6:** Spanning tree example

BPDUs that it would transmit on that port. When comparing the BPDUs, we use the following rules:

- A BPDU with a lower root bridge ID is “better” than any other BPDU with a higher root bridge ID.
- If the above rule results in a tie (i.e., the root bridge ID is the same), then a BPDU with lower cost is “better” than any other BPDU with higher cost.
- If both the above rules result in a tie (i.e., the root bridge ID and cost are the same), then a BPDU with a (numerically) lower transmitting bridge ID is “better” than any other BPDU with a higher transmitting bridge ID.
- If all three rules above result in a tie (i.e., the root bridge ID, cost, and transmitting bridge ID are the same), then a BPDU with a lower transmitting port ID is “better” than any other BPDU with a higher transmitting port ID.

Examples:

$\langle 29 \rangle . \langle 15 \rangle . \langle 35 \rangle . \langle 0 \rangle$ is better than $\langle 31 \rangle . \langle 12 \rangle . \langle 32 \rangle . \langle 1 \rangle$
 $\langle 35 \rangle . \langle 15 \rangle . \langle 80 \rangle . \langle 2 \rangle$ is better than $\langle 35 \rangle . \langle 18 \rangle . \langle 38 \rangle . \langle 1 \rangle$
 $\langle 35 \rangle . \langle 80 \rangle . \langle 39 \rangle . \langle 1 \rangle$ is better than $\langle 35 \rangle . \langle 80 \rangle . \langle 40 \rangle . \langle 0 \rangle$
 $\langle 35 \rangle . \langle 15 \rangle . \langle 80 \rangle . \langle 0 \rangle$ is better than $\langle 35 \rangle . \langle 15 \rangle . \langle 80 \rangle . \langle 1 \rangle$

3. If a bridge receives a BPDUs on a port that is better than the one that it would have transmitted on that port, it no longer transmits BPDUs on that port (that port will be named as either root port or blocked port). Therefore, when the algorithm stabilizes, only one bridge on each segment (the designated bridge for that segment) transmits BPDUs on that segment.

Based on the received BPDUs from all interfaces, each bridge independently determines the identity of the root bridge (which will eventually converge to a single identity). After receiving BPDUs, the bridge ID of the “newly determined” root bridge is therefore the minimum of a bridge’s own bridge ID and the root ID contained in all other received BPDUs. Each bridge is able to determine its lowest cost to the root, its root port, and its designated ports, if any.

As an example, assume that bridge B has a bridge ID of 18. Suppose that the “best” BPDU received by bridge B on each of its ports is as given in Table 3.

From the best BDPUs received by bridge B on its ports, it is clear that both port 1 and port 2 received BDPUs containing the lowest root ID. Bridge B has bridge ID 18, which is greater than 12. Therefore, bridge B is not the root bridge, and after B receives the BDPUs listed in Table 3, bridge B now believes that bridge 12 is the root bridge. Bridge B must also determine the cost to the root bridge; this cost is calculated by adding 1 to the lowest cost reported to bridge 12 by any of the best BDPUs given in Table 3. Likewise, bridge B must also select its root port—the port through which the root bridge can be

Table 3: Examples of the Best BPDUs Received on Each Port

Port Number	Best BPDU Received on the Port
Port 1	<12>.<85>.<51>.<0>
Port 2	<12>.<85>.<32>.<2>
Port 3	<81>.<0>.<81>.<1>
Port 4	<15>.<31>.<27>.<1>

reached via the smallest cost. Because the BPDUs received at ports 1 and 2 report the same cost to root (i.e., 85), the cost to root for bridge B is $1 + 85 = 86$, and because the transmitting bridge ID is lower in the BPDU received at port 2, bridge B selects port 2 as its root port. Bridge B no longer transmits BPDUs on port 2.

Bridge B now constructs a BPDU <12>.<86>.<18>.<possible port number on bridge B>. This BPDU is better than the ones received at ports 3 and 4, so bridge B becomes a designated bridge for the two LAN segments, one connected to port 3 and the other to port 4. Ports 3 and 4 are the designated ports, and bridge B continues to transmit BPDUs on these ports.

Finally, the BPDU that bridge B would send out is not better than the BPDU received at port 1. Port 1 is, therefore, blocked; bridge B no longer transmits BPDUs out of this port.

Thus, bridge B has determined the following:

- the root bridge and bridge B's root port (bridge 12 and port 2),
 - its own distance (cost) to the root (86),
 - ports for which it is designated (3, 4), and
 - blocked ports (1).
4. At each step, a bridge must decide which ports to include in the spanning tree and which ports to exclude. The root port and all designated ports are included, whereas all blocked ports are excluded. Thus, in the above example, ports 2, 3, and 4 are included in the spanning tree while port 1 is excluded.

Bridges place all ports included in the spanning tree in the “forwarding” state. A bridge receives and transmits frames on ports in the forwarding state. Bridges, however, neither accept nor transmit data on blocked ports (this does not apply to BPDUs).

By having all bridges run the same algorithm, a spanning tree will be formed that connects every LAN segment into a loop-free tree. Data frames can therefore be transported along the branches of the tree.

Address Learning and Frame Forwarding

When a data frame arrives at a port on a bridge, the bridge must determine on which outgoing port the frame should be transmitted. The decision is made using the aforementioned forwarding database, which is simply a table

Figure 7: Application of STP

containing the destination MAC addresses and the appropriate output port that should be used to reach those destinations.

To maintain the FDB and forward frames correctly to the destinations, a bridge will use the following procedure.

1. When a bridge receives a frame, the bridge stores the frame's source address in the forwarding database along with the port on which the frame was received.
2. The bridge then looks up the frame's destination address in the forwarding database:
 - If the destination address is found, the bridge forwards the frame on the outgoing port specified in the forwarding database (except when the frame is received from the same port).
 - If the destination address is not found, the bridge forwards the frame on all of the outgoing ports except for the one on which the frame was received.

STP Example

We notice that the spanning tree algorithm is simply a distributed version of the shortest-path algorithm: Once a root bridge is determined, the shortest paths from every other bridge to the root bridge are included in the active topology. To illustrate the application of the STP, consider the topology shown in Figure 7.

For this topology, we demonstrate the step-by-step procedure used by the spanning tree protocol and algorithm in a sequence of diagrams. In each diagram, we show one full cycle of the exchange of BPDUs. Progressing through these cycles, the topology converges to a final loop-free topology (the last in the sequence of diagrams). In each cycle, we also indicate BPDUs exchanged between bridges (without being particular about the port numbers for selecting the best BPDU). The sequence is shown in Figures 8 and 9.

Reconfigurations and STP

One goal of the spanning tree protocol is to allow for the formation of a new spanning tree in case the extended LAN topology changes. Topology changes are part of regular LAN operation, with segments and bridges added, removed, or moved around in the topology. These changes may also result by upgrading a segment to run at a higher speed (e.g., from 100 Mb/s to

1 Gb/s). Sometimes, a topology change also occurs when a segment or a bridge (or another LAN device) malfunctions. The STP should deal with topology changes efficiently and quickly find a new spanning tree.

For spanning tree maintenance, the STP acts as a *soft state protocol*, which means that bridges must be periodically assured of the health of the LAN topology. For this purpose, in addition to the best configuration message received at each blocked or root port, bridges store an *age field*. The bridge continues to increment the age field until a configuration BPDU is received, at which time the age field is reset. Otherwise, the age field reaches the *MaxAge*, at which point the bridge assumes that the topology has changed and consequently runs the STA from the start.

Under normal operation, the root bridge generates and then transmits the configuration BPDUs at every *hello time* with the age field set to zero within the message. When any downstream bridge receives a message coming from the root (received at the root port), it transmits a BPDU on designated ports with the age field set to zero within the message. Thus, if the root bridge fails or the path to the root bridge becomes unavailable, a bridge stops receiving fresh messages and eventually times out (the age field becomes equal to *MaxAge*) at which point the root bridge, cost to the root bridge, and the root port are all calculated from scratch. Although timing out on root ports will always cause everything—root, cost to root, and root port—to be recalculated, timing out on a blocked port may or may not indicate a significant change in topology and thus may not warrant a fresh running of the spanning tree protocol.

Reconfigurations and Loops

When an extended LAN undergoes a topology change and reconfiguration, different ports of the bridges change their state. The blocked ports (across which data frames were not allowed in an active topology) may now be required to change their state to forwarding (by becoming root or designated ports). Similarly, ports that were previously in the forwarding state may now be required to move to a blocking state. Because the STP converges after some iterations, it is possible that temporary loops and temporary disconnections will appear, even though the new final topology is guaranteed to be loop-free. Even if they are temporary, loops cause frame proliferation, and therefore it is desirable to avoid temporary loops in a changing topology. The STP used in bridges ensures that loops are avoided by forcing ports in the blocking state to wait for some time before switching to the forwarding state. This wait period is set to be large enough to allow the topology change information to propagate through the network. Obviously, a port that needs to move to the blocking state in the new topology from the forwarding state in the old topology is allowed to switch state immediately. This may cause temporary disconnections, resulting in frame drops, which is an acceptable LAN behavior as reliable delivery of data is left to the higher layer protocols.

When a port is being moved from the blocking state to the forwarding state, the IEEE 802.1D standard defines two intermediate states during the wait period (see IEEE Standards Committee 2004). In the *listening*

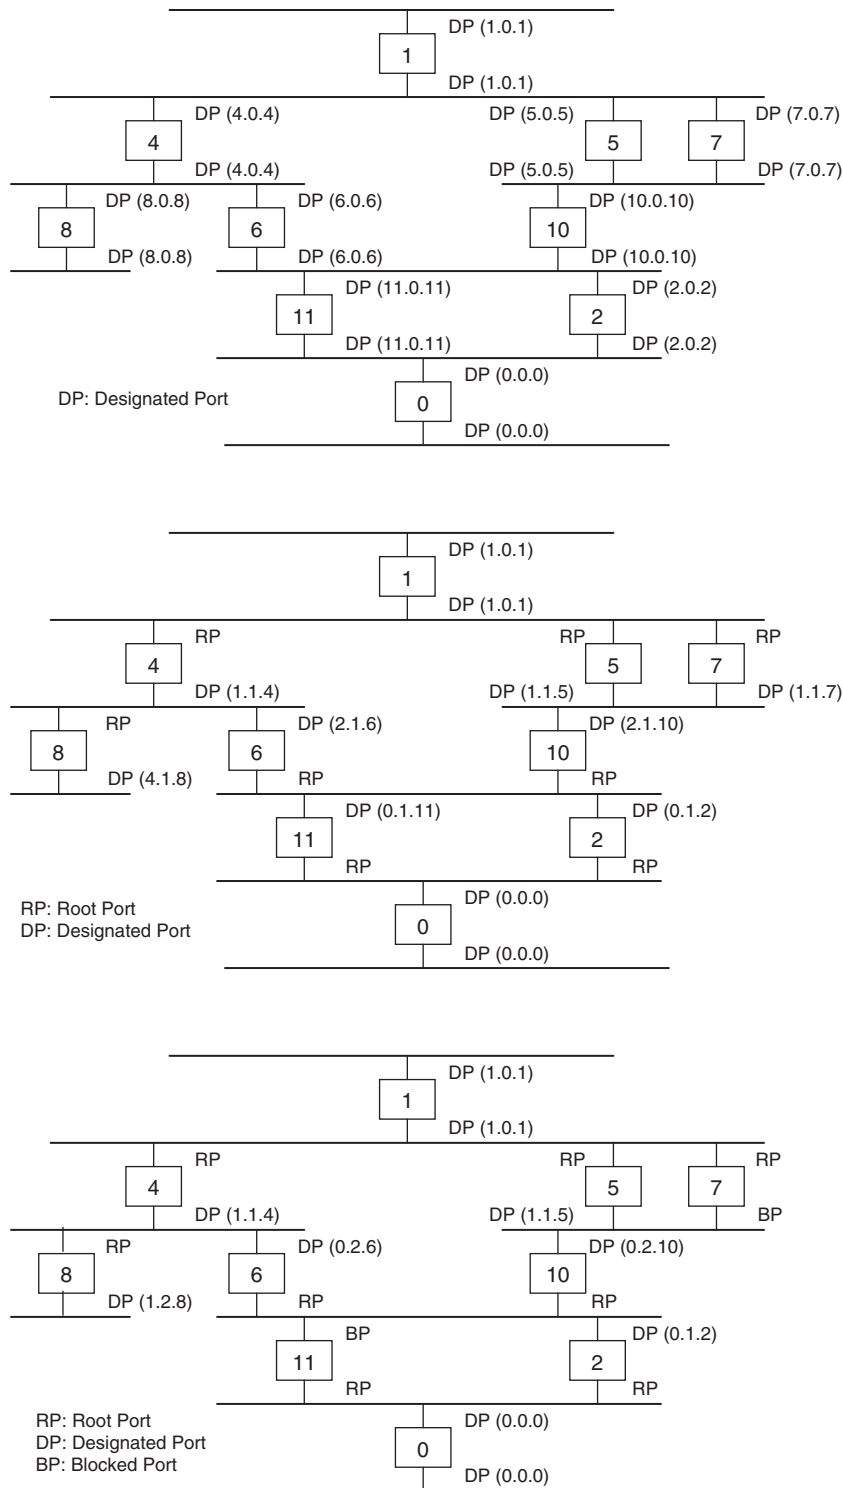

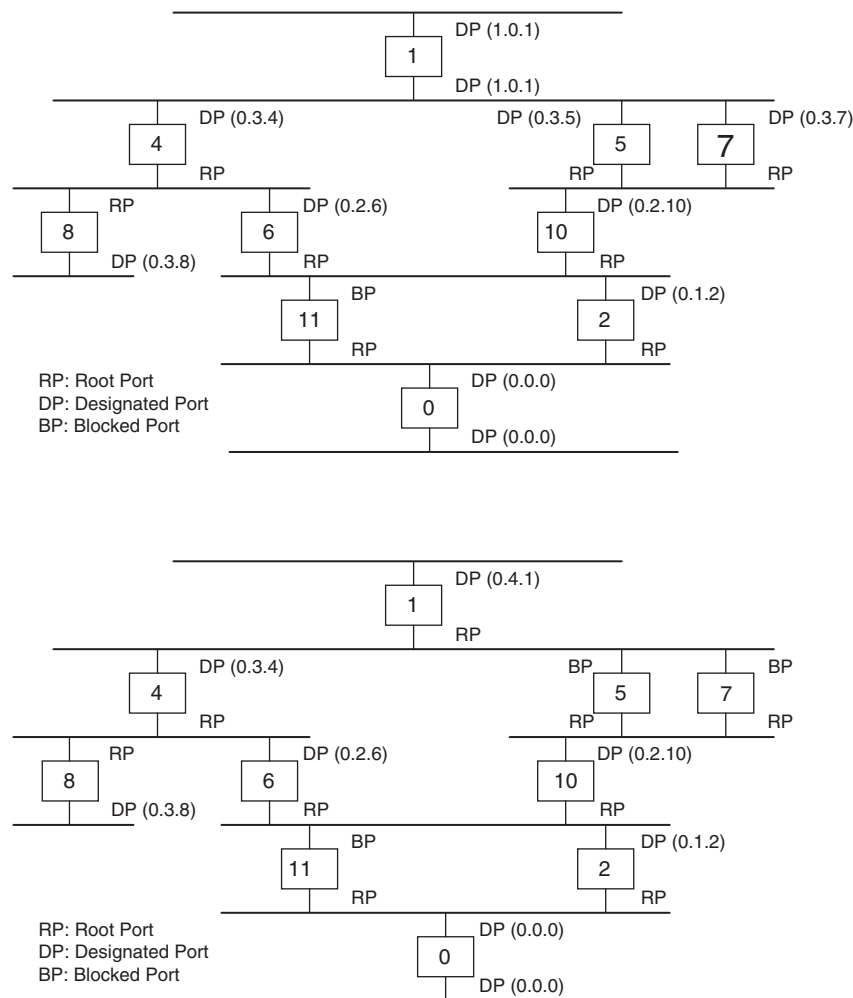

Figure 8: Applying STP, part 1

intermediate state, the bridge listens but does not learn station addresses through that particular port; in the *learning* intermediate state, address learning is enabled. In both intermediate states, bridges do not forward any data frames. A state diagram reproduced from the IEEE 802.1D standard depicting state transitions from blocking state to forwarding state is shown in Figure 10.

BPDU Format

The configuration BPDUs exchanged between bridges for the operation of the STP have a generic format as given in Figure 11. The TC flag in the bridge message format indicates a *topology change*. When a bridge notices that a port has moved into or out of the blocked state, it transmits

a topology change notification on the segment connected to its root port (by setting the TC flag). The bridge designated on that segment (which receives the topology change notification on the designated port) sets the *topology change acknowledgement* (TCA) flag in the next BPDU transmitted onto that segment; this is done to inform the bridge that has launched the topology change notification that action is being taken about the reported topology change. In addition to sending an acknowledgement (by means of TCA flag) to the bridge indicating the topology change, this bridge also relays the topology change notification on its own root port toward the root bridge. In this manner, the topology change notification reaches the root bridge, which sets the TC flag in its BPDUs for a time period equal to the sum of MaxAge and *forward delay*. The forward delay time is a network-wide parameter that indicates the longest distance between any two bridges in the extended LAN, and it may be set by the network manager to ensure that the topology change notification

is propagated to all of the bridges in the extended LAN before a port is actually moved from the blocking state to the forwarding state.

BRIDGES AND LAN MULTICAST

When a source intends to send a frame to multiple receivers, a naive solution is to broadcast the frame throughout the extended LAN so that it is transmitted on every segment and received by all of the hosts. Hosts that are interested in this frame pass it to their higher layers, while hosts that are uninterested in this frame drop it at the link layer. This solution has some inherent problems. First, broadcasting multicast traffic over slower links might cause those links to saturate. Second, transmitting a message to a large number of stations in an extended LAN when it is only intended for a few stations does not seem to be a reasonable option, even if all the links in the LAN have high capacity.

- 1) Port Enabled → Management
- 2) Port Disabled → Management or failure
- 3) Selected as RP or DP
- 4) Ceases to be RP or DP
- 5) One forward delay elapses

A solution to disseminate multicast traffic only through those portions of the LAN where it is actually required is to allow the end stations or hosts to explicitly indicate their interest in receiving traffic on given multicast addresses. Entries for multicast addresses are entered into the same filtering database that is used to forward or filter unicast addresses. Such multicast entries may either be added statically by a network manager or entered dynamically by using a protocol derived from *group attribute registration protocol* (GARP) (see the following section) called *GARP multicast registration protocol* (GMRP). If a bridge only allows static multicast entries (that may be manually entered), the bridge is said to be providing *basic filtering services*. In contrast, the provision of *extended filtering services* requires that the bridge also allows

that dynamic multicast forwarding entries be entered into the FDB. In either case, a bridge must allow static unicast entries (entered manually) as well as dynamic unicast entries (through the address learning process). A bridge conforming to the IEEE 802.1D standard must provide basic filtering services and may optionally provide extended filtering services.

As with unicast FDB entries, multicast forwarding entries in a bridge's FDB enlist the set of ports on which a frame should be forwarded, indicating the presence of at least one end station, approachable through a listed port, that is interested in receiving that particular multicast frame. Thus, each port of a bridge keeps track of the interest of end stations that may be accessible through that port. Note that if multiple end stations, accessible through a port of a bridge, are interested in receiving a multicast frame, it is only necessary for the bridge to transmit just one copy of the frame on that port.

End stations indicate their interest in receiving a frame destined for a specific multicast address using GMRP. Although the details encompassed by GMRP are too many to describe here (see the IEEE 802.1D standard in IEEE Standards Committee 2004)), GMRP includes mechanisms that allow end stations to register (i.e., indicate interest in a multicast group address) or deregister membership information with the bridges attached to the same LAN segment. GMRP also allows bridges to disseminate multicast group registration information throughout the extended LAN. For each bridge in the extended LAN, a port is marked to forward a multicast frame on a port if at least one member of that multicast group is accessible through that port. Similarly, forwarding of multicast traffic on a port is retracted when all members of the multicast group that are accessible through that port have deregistered.

As a result of GMRP operation, frames sent to a particular multicast group address can be received on all LAN segments to which at least one end station that is interested in receiving frames sent to that multicast group address is attached. A multicast frame is also transmitted on those LAN segments that are on the way (i.e., along the active topology) from the source of the multicast frame to any intended recipient of that frame. Note that the source of a multicast frame may reside anywhere in the topology and may not need to explicitly register for that multicast address unless it also wishes to receive frames sent to that multicast address. Thus, any station that wishes to send frames to a particular group can do so from any point of attachment in the extended LAN. This property is sometimes referred to as the *open host group concept*.

GENERIC ATTRIBUTE REGISTRATION PROTOCOL

As described in the preceding section, dissemination and distribution of interest in a particular multicast group is a function of GMRP for which it uses GARP. In fact, GARP may be used to register for and disseminate information about any generic attribute in a bridged LAN. A multicast group address is just one example of a generic

attribute. Thus, GMRP may be considered as an application that uses GARP service. Another application that uses the services of GARP, in much the same way that GMRP does, is *GARP VLAN registration protocol* (GVRP). GVRP uses the services of GARP to disseminate information about *virtual LAN IDs* (VLAN IDs), which is another generic attribute. The attributes registered, deregistered, or propagated through GARP are opaque to GARP itself in the sense that it is up to the application (such as GMRP or GVRP) to interpret a generic attribute.

GARP Operation

The two principal control messages used in GARP to register (or deregister) an attribute are *join message* and *leave message*. Join message is initiated by an end station (and relayed by the bridges) to register an attribute. Leave message is initiated by an end station (and relayed by the bridges) to deregister an attribute.

There are other messages that are derived from these two principal messages, details of which can be found in the IEEE 802.1D standard. The join and leave messages are initiated by end stations to register or deregister for a particular attribute (a VLAN ID or a multicast group address).

As previously mentioned, if multiple end stations, all accessible through a port of a bridge, are interested in receiving a multicast frame, then it is only necessary for the bridge to transmit just one copy of the frame on that port. Thus, if there are multiple end stations on a single segment, all interested in a given attribute, only one of them needs to register for the said attribute. This indicates to the bridges connected to that segment that there is at least one end station on this segment that is interested in receiving frames corresponding to the given attribute, and thus the bridges will forward the frame on their ports attached to this segment. In contrast, a bridge will not forward a frame with given attributes on a given port if no one has indicated an interest in that attribute from that port, indicating that none of the interested recipients is accessible through this port.

For each bridge that implements an application that uses GARP, a *GARP participant* exists at each port for each application (such as GMRP or GVRP). Each GARP participant further consists of a *GARP application* component and a *GARP information declaration* (GID) component. Although the application component has more to do with the application (attribute type and values, how to send frames to the application, etc.), the GID component is more relevant with the actual declaration (register and deregister) and dissemination of an attribute. The GID component further consists of two state machines: (1) an *applicant* state machine that keeps track of the interest level of end stations in a given attribute and (2) a *registrar* state machine that allows the bridge to selectively forward (or filter) a frame for a given attribute. When someone registers for an attribute, the associated registrar at the port, after listening to the registration message, should be moved to a state (IN) for that attribute. While in the IN state for an attribute at a given port, the bridge should forward the frames on that port for that attribute. A leave message (or a time-out) for a given attribute on a given

port should cause the registrar move to a state labeled MT, indicating that there is no need for the bridge to forward a frame with that attribute on that port.

Virtual LANs and GVRP

An extended LAN may span a large campus covering a large subnetwork with many end stations. It is likely that people in one department are not interested in receiving frames that really belong to another department. This calls for the formation of *virtual LANs* (VLANs) on the active topology such that the unicast, multicast, or broadcast traffic remains limited to a portion of the active topology (the VLAN). Thus, a VLAN is a collection of LAN segments and end stations connected to them within an extended LAN that has exactly the same properties of an independent LAN (Seifert 2000). In an extended LAN comprising several VLANs, traffic belonging to a VLAN is restricted from reaching users in other VLANs.

End stations indicate their interest in one or more VLANs by sending register message for those VLANs on the segments to which they are attached. The register message includes the generic attribute, which, in this case, is the VLAN ID. Differentiation among traffic belonging to different VLANs is accomplished by the addition of VLAN tags (VLAN ID or VID) to frames; bridges use VIDs to appropriately filter the frames.

The VID is attached with a frame as an additional data called a *tag*. A tag consists of sixteen bits, twelve of which are used for the VID. It is expected that VLAN deployment in a bridged LAN is incremental so that some station will still be VLAN-unaware. Such legacy stations are not able to handle the VLAN tags. Thus, VLAN-aware bridges must ensure that tagged frames (frames that include VLAN tags) are untagged before they are forwarded to a legacy station. Thus, each bridge maintains a set of ports called *untagged set* that consists of ports through which frames that are transmitted shall be sent untagged. In other words, a bridge removes the tags (if already present) from the frames before forwarding them to any port that is included in the untagged set.

The actual realization of a VLAN is made possible by means of another set called the *member set*, which consists of those ports that are included in a given VLAN. Each bridge maintains a member set corresponding to each VLAN. Because a VLAN is a subset of the spanning tree, none of the blocked ports may be included in any member set of any bridge. In an extended LAN where all bridges are VLAN-aware, traffic belonging to a VLAN is restricted to that VLAN and is not allowed to leave the VLAN.

A VLAN is also represented by a tree (a VLAN is a subset of spanning tree, and different VLANs may overlap) that is confined to some (or all) of the nodes (bridges) in the extended LAN. Forwarding and filtering of frames on a VLAN is quite similar to how it is done if VLANs are not implemented. However, learning is done on each VLAN independently. In other words, for each VLAN, the port through which particular end stations can be reached is determined and entered into the FDB for that VLAN. Sometimes, shared learning on multiple VLANs is also desirable and can be configured using another parameter (FID) of bridges. Many commercial bridges available

these days are VLAN-aware, and their VLAN capabilities are frequently used.

CONCLUSION

Bridges are an essential part of today's local area networks. They allow a LAN to scale from a small building to a large campus, as well as from a few stations to a large number of stations. Bridges perform learning to avoid unnecessarily forwarding data traffic onto LAN segments. This selective forwarding can also be used to register specific attributes with the bridges such that traffic corresponding to a multicast group or a virtual LAN is forwarded to the appropriate interfaces.

A *spanning tree protocol* (STP) is used by the bridges to determine the active topology over which data frames will flow in an extended LAN. Recent versions of STP include *rapid spanning tree protocol* (RSTP) (Cisco 2006), which results in faster convergence to a final spanning tree after a topology change. This is possible by allowing ports to move from blocked state to forwarding state a bit sooner. Another variation of STP is *multiple spanning tree protocol* (MSTP) (Cisco 2007), which uses overlapping multiple spanning trees, each with its own root bridge, to efficiently utilize the LAN segments in an extended LAN.

Traditionally, bridges are considered as the devices that just extend the scope of a local area network in a given campus, while different campuses are connected to each other using routers (Kurose and Ross 2004). However, advances and cost-effectiveness of Ethernet technology has led to the use of Ethernet standards over a larger metropolitan area (Metro Ethernet Forum 2007). In this case, subscribers or branch offices of a larger business may be connected using bridges, thus forming a LAN that covers an entire metropolitan area.

GLOSSARY

Active topology: A topology comprising portions of a bridged LAN over which transmission of data is allowed. Control traffic is usually used to obtain an active topology and may be transmitted over portions of the local area network that are not part of the active topology.

Bridge: A layer 2 packet switch that receives a frame from any of its interfaces and appropriately forwards that frame to some of its other interfaces.

Bridge protocol data unit (BPDU): A frame that is used to exchange control traffic between bridges that run the spanning tree protocol.

Broadcast domain: The extent of an extended LAN. All devices in the same broadcast domain can be reached by sending a frame to the data link layer broadcast address.

Carrier sense multiple access with collision detection (CSMA/CD): A multi-access protocol in which each transmitter senses the carrier before transmission and also uses a mechanism to detect a collision.

Collision domain: The extent of a physical medium in which two or more frames cannot coexist without interfering.

Designated bridge: The bridge responsible for relaying data frames on a given LAN segment. A given bridge may be designated for multiple LAN segments.

Extended LAN: A conglomerate of LAN segments joined by bridges.

Forwarding database (FDB): In a bridge, a table that lists the forwarding information and maps a destination MAC address to a set of outgoing ports.

Frame: A formatted block of data sent from one node to an adjacent node in a computer network. A frame is an entity that is dependent upon the link layer technology.

GARP multicast registration protocol (GMRP): Protocol used to register and deregister multicast group addresses in a bridged LAN for which an end station or a bridge is interested in receiving data traffic.

Generic attribute registration protocol (GARP): Protocol used to register and deregister attributes whose corresponding data traffic is of interest to a bridge or an end station.

GVRP GARP VLAN: Registration protocol used to register and deregister *virtual local area networks* (VLANs) in a bridged LAN.

Hub: A LAN device that connects two or more LAN segments, usually on separate collision domains. It does not run the spanning tree algorithm or perform any learning on these segments. A hub broadcasts a frame received on a port to all of the other ports.

Local area network (LAN): Used to signify either a LAN segment or an extended LAN.

Logical link control (LLC): The upper sublayer of the data link layer. It is independent of the underlying physical layer and acts as an interface between the MAC layer and the network layer.

Media access control (MAC): The layer in a layered network architecture that provides an addressing and channel access control mechanism to many nodes connected to the same physical media.

Packet: A formatted block of data carried by a computer network from one node to another.

Packet switch: A network device that receives packets from any of its incoming interfaces and appropriately forwards it to some of its outgoing interfaces based on the information contained in the packet header.

Repeater: A LAN device that connects two or more LAN segments, usually on the same collision domain. It does not run the spanning tree algorithm or perform any learning on these segments. A repeater broadcasts a frame received on a port to all of the other ports.

Root bridge: The bridge with the lowest identification number.

Router: A layer 3 packet switch that forwards layer 3 packets based on the information in the packet header.

Spanning tree: A loop-free active topology that traverses all the bridges in a bridged LAN comprising a set of LAN segments connected by the bridges. A spanning tree is obtained by using the spanning tree protocol.

Spanning tree algorithm (STA): The algorithm used by the spanning tree protocol to find a spanning tree

that can be used as active topology in a bridge's local area network.

Spanning tree protocol (STP): The protocol used to find a spanning tree in a bridged local area network.

Transparent bridge: Bridges are transparent in the sense that two stations on two different segments of an extended LAN, formed by using transparent bridges, communicate as if they are on the same LAN segment.

Virtual local area network (VLAN): A subset of a bigger local area network. Data traffic in a VLAN is confined within the subset that represents the VLAN.

INTRODUCTION

Increases in the performance of *large-scale integrated* (LSI) circuits have enabled the amount of data that can be input or output from an LSI chip to be dramatically increased. Concurrent with these technological innovations has been increasing demand for high-speed data link systems that use high-speed interface LSIs capable of speeds in the gigabit-per-second (Gbps) range. These improvements in interface performance lead to better system performance for computers and networks. Although LSI performance increases with device miniaturization, design innovations are also needed to get the most out of device performance. A multivalue transmission technique using *pulse amplitude modulation* (PAM) is one candidate for overcoming these limitations and increasing the effective data bandwidth.

This chapter reviews several approaches for improving communication performance. First, the building blocks of communication LSIs and the trends underlying the development of high-speed communication LSIs are shown. PAM is then introduced, and its advantages and disadvantages are discussed by comparing it with nonmodulated data transmission or normal binary *non-return to zero* (NRZ) signal transmission. Finally, the likely appreciations of data transmission using the multivalue transmission technique are presented.

COMPONENTS FOR HIGH-SPEED INTERFACE

Figure 1 shows the system components of a serial communication system: transmitter (TX), channel, and receiver (RX). The TX converts several bitwide digital information streams into a single bitwide signal, or *serial signal*, in the transmission medium or communication channel. For electrical communication, the most commonly used channels are a board trace, coaxial cable, and twisted-pair cable.

Figure 1: System components

An optical fiber is used for optical communication. The RX at the other end of the channel receives the transmitted signal and restores the original digital information.

Examples of block diagrams of the TX and RX are shown in Figures 2 and 3, respectively. The TX is composed of a data-generation block (*encoder*), serializer (*multiplexer*, or MUX), and driver (*output buffer*). The encoder receives multi-bitwide data and regenerates encoded data to increase not only the transmission accuracy but also the operating margin of the receiver; for example, an 8B10B encoder is widely used in high-speed interface specifications because it guarantees DC balancing and a maximum run length of five for the serial data in the channel. The encoded data are then serialized into high-speed serial data by the MUX and output by the output buffer. A differential output buffer is often used for the output buffer because of its high tolerance to noise. A frequency synthesis *phase-locked loop* (PLL) generates a high-speed clock signal from a low-speed reference signal.

The RX is composed of a data receiver (*input buffer*), data recovery block (*clock and data recovery*, or CDR),

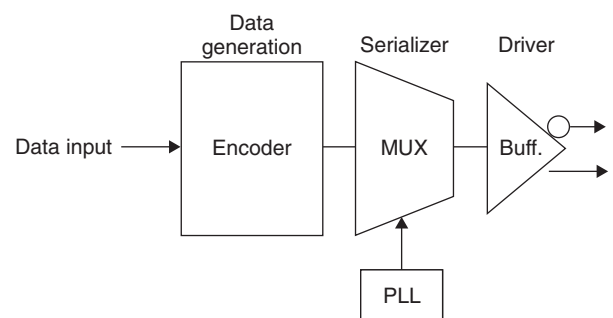

Figure 2: Transmitter block diagram

Figure 3: Receiver block diagram

circuit), deserializer (*demultiplexer*, or DEMUX), and digital data restorer (*decoder*). The input buffer converts the small swing signals on the channel to a full-swing signal to be handled in the RX circuit. The high-speed serial data must be sampled at the optimal phase clock signal, so the CDR adjusts the clock signal phase. The recovered data are then deserialized by the DEMUX and restored to the original digital data by the decoder; for example, the 10B8B decoder is used for the 8B10B encoder.

There are two important issues related to achieving high-speed data transmission: (1) high-speed signaling to transmit high-speed data and (2) high-speed chip operation, especially clock generation and timing recovery. The high-speed signaling is mentioned in detail in the following sections. The clock and timing issue, which is very important for accurate signal transmission and reception, is introduced next. Briefly here, the jitter of the clock generator in the TX, like that of the PLL, is directly transferred to the output signal, where it degrades the transmitted waveform. The timing recovery circuit (the CDR in Figure 3), which is often embedded in the RX, adjusts the phase of the clock in the RX to sample the transmitted signal at the optimal position.

REQUIREMENTS FOR WIRED COMMUNICATION

There are three approaches to address the demand for greater transmitted data volumes: (1) increase the number of channels, (2) increase the data-transmission speed, and (3) increase the transmission efficiency. Increasing the number of channels leads to the cost being multiplied by the number of channels. Therefore, it is more cost effective to increase the speed because this does not need an increase in the number of channels. The available increasing in data-transmission speed, however, is limited by the performance of devices and channel medium.

Although semiconductor device performance has increased with miniaturization, the circuit operating speed cannot be increased as the data rate is increased. To overcome this limitation, a parallel architecture has been proposed (Figure 4). Compared with the conventional single architecture (Figure 4a), which requires a clock signal of the same frequency as the transmitted data rate (e.g., a 10-GHz clock signal is necessary for 10-Gbps transmission), the parallel architecture shown in Figure 4b overcomes device limitations by using multiple clocks with different phases. In this parallel architecture, the clock frequency decreases as the number of different-phase clocks increases. As the number of multiphase clocks increases, the clock frequency can be decreased. This approach, however, requires highly precise clock-phase control because any distortion of the phase differences directly increases the jitter of the output data.

The trends underlying the development of high-speed serial data communication LSIs that incorporate *complementary metal oxide semiconductor* (CMOS) technology are shown in Figure 5. The transmission data rate has been increased in proportion to reductions in the gate length: operating speeds of 1 and 3 Gbps have been achieved with 0.8- μm to 0.5- μm and 0.15- μm CMOS devices by using

Figure 4: Serializer and deserializer architectures

Figure 5: Transmission performance trends

the single architecture and normal *two-level pulse amplitude modulation* (2-PAM) or NRZ signaling. The maximum transmitted data rate is determined by the device performance and will be only about 4 to 5 Gbps for a 0.1- μm CMOS. In contrast, the parallel architecture overcomes device performance limitations by using multiple different-phase clocks. For example, a 4-Gbps data rate is achieved with a 0.25- μm CMOS, and a 6-Gbps data rate with a 0.18- μm CMOS. The maximum transmitted data rate reaches more than 10 Gbps with a 90-nm CMOS.

The channel performance limitation depends on the size and construction of the channel material such as the conductor and dielectric materials. For example, Figure 6 shows the transmission medium performance of a *printed circuit board* (PCB) with a 1-m long trace; it shows received data amplitude versus transmission

Figure 6: Transmission medium performance

speed. Signal attenuation increases with frequency. The attenuation derives from the medium's series resistance, which is caused mainly by the skin effect and dielectric loss. Figure 6 indicates that high-speed data are received as a small-amplitude signal. For example, when 10-Gbps NRZ data is transmitted with a 1-V swing at the transmitter, the received data amplitude is attenuated to less than 50-mV. The channel performance, moreover, depends on channel length. If we want to increase system performance while continuing to utilize existing system equipments, the transmission data speed will need to be increased while the same channel medium or channel performance and length is kept. However, the received data's amplitude decreases and they cannot be received at the RX because of channel performance degradation. This means that the improvements in data volume that can be achieved by increasing the data speed are limited.

Therefore, the third approach—increasing transmission efficiency—is expected to be effective at improving the transmitted data volume. As mentioned with Figure 5, a higher speed can be achieved by using four-level PAM (4-PAM) signaling, which is more efficient than 2-PAM (NRZ) signaling. A data rate of 10 Gbps has been achieved with 0.4- μm technology, and more than 20 Gbps has been reached with 90-nm technology. The figure indicates that the maximum data rate is dependent on the circuit design (e.g., a parallel architecture) and data signaling (e.g., PAM) rather than on the design rule or gate length. PAM, especially, has been found to be more effective at increasing the data rate in low-speed devices.

To summarize the requirements for high-speed serial data transmission, the transmitted data volume is limited by the transmission medium performance more than by device performance. This means that improving transmission efficiency, or decreasing the effective data speed on the transmission medium, is important for increasing the data volume or improving system performance.

DATA SIGNALING

This section introduces data signaling to decrease the effective data speed on the transmission medium.

Figure 7: PAM signaling—(a) 2-PAM and (b) N-PAM

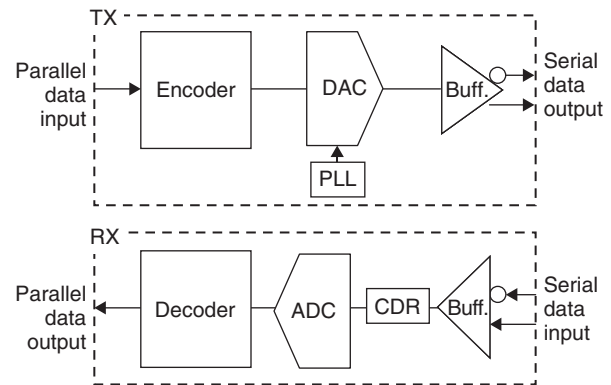

Figure 8: Block diagrams for PAM transmitter and receiver

Transmitting multiple bits in each transmit time decreases the required data rate for the channel. The simplest multilevel transmission scheme is pulse amplitude modulation. The waveform of the N -level pulse amplitude modulation (N-PAM) is compared with 2-PAM or NRZ signaling in Figure 7. In N-PAM, each symbol time comprises $\log(N)/\log(2)$ bits of information. This means that the same data rate can be achieved with a low effective transmission speed on the channel or a higher data rate can be achieved with the same effective speed. For example, the data rate per channel reaches 10 Gbps with 4-PAM when 0.4- μm CMOS is used, although it is approximately 4 Gbps with an eight-phase parallel architecture using the same technology. And it reaches more than 20 Gbps with 90-nm technology. As the amplitude modulation level is increased, the total volume of the transmitted information can be increased.

The PAM scheme requires a *digital-to-analog converter* (DAC) for the TX and an *analog-to-digital converter* (ADC) for the RX, as shown in Figure 8. The serializer in the serial interface TX is replaced with a modulator, or DAC. In the RX, the deserializer is replaced with a demodulator, or ADC. Any effort to increase the volume of the transmitted information confronts with two challenges: increase the transmission data rate and increase the amplitude modulation level. Increasing the amplitude modulation level requires a high *signal-to-noise ratio* (SNR) for the DAC and ADC. On the other hand, if we increase the data rate, then high-speed operation is mandatory for the DAC and ADC because they are located in the last stage of the TX and the first stage of the RX, respectively, and both operate at the highest speeds in the system. Moreover, both the DAC and ADC have a trade-off between higher data

Figure 9: Comparison between NRZ and 4-PAM signaling

Figure 10: Waveform with noise

throughput and higher SNR. Taking this trade-off into account, 4- to 5-PAM transmission is reasonable at the Gigahertz bandwidth.

The logic level of a 4-PAM transmitted waveform is compared with NRZ in Figure 9. In 4-PAM, each symbol time comprises two bits of information. Therefore 4-PAM reduces the data rate to half that of an NRZ transmission; in other words, twice the data rate can be achieved with the same bandwidth. The voltage swing of 4-PAM is one-third that of an NRZ transmission.

We now consider the problem of a signal contaminated by additive noise, as represented by the receiver diagrammed in Figure 10. To receive transmitted data, we should sample it at a position close to the center timing of the transmitted data. The signal amplitude is variable because of noise: The difference between ideal data and actual data that contain noise represents the amplitude error. The signal transit timing is also variable because of noise: The difference between ideal data and noised data at the center of the signal amplitude is the time-position error. Figure 11 shows a generalized NRZ signaling eye pattern with noise. Here, only *additive white Gaussian noise* (AWGN) is considered; another large noise source, *intersymbol interference* (ISI), is discussed later. The optimum sampling time corresponds to the maximum eye opening. Noise partially closes the eye and thereby reduces the noise margin. When synchronization between the received data and the sampling timing is derived from the zero crossings of the received data, zero-crossing distortion because of noise produces jitter in the receiver clock, which determines the sampling timing, and results in nonoptimum sampling times. The slope of the eye pattern in the vicinity of the zero crossings indicates the sensitivity to timing error.

Figure 11: Generalized NRZ eye pattern

Figure 12: Transmitted voltage levels and reference voltage (V_{ref}) levels—(a) binary modulation and (b) 4-PAM

When the amplitude error for an ideal data pattern is assumed to be almost the same independent of signaling, such as NRZ or multilevel PAM, the large received data amplitude leads to the large noise margin. The received data amplitude is considered here. Examples of signal voltage levels obtained for NRZ and 4-PAM transmissions are shown in Figure 12. The reference voltages (V_{ref} , V_{refH} , and V_{refL}) are necessary to determine the correct data for 4-PAM transmission, while NRZ transmission does not always need the reference voltage because the difference in signals can be used to determine data. The voltage difference input to the voltage detector is equal to the full voltage swing under ideal conditions in NRZ transmission. The difference in 4-PAM transmission is equal to the difference between the input and reference voltages: it is one-sixth that of NRZ transmission when the reference voltages are set at the midpoint of the PAM levels. The voltage margin of PAM transmission is therefore less than one-sixth that of NRZ transmission. When a differential input buffer is used to receive 4-PAM, the voltage margin of PAM is one-third that of NRZ.

Figure 13 shows an eye diagram for data received through a channel with loss where ISI is not considered. The transmission data rate is the same for NRZ and 4-PAM signaling in this comparison. Therefore, the attenuation was set at -20 dB for NRZ signaling and -10 dB for 4-PAM signaling because channel loss is usually proportional to the transmission speed. In this case, the received eye diagram was reduced to 80 mV for NRZ signaling with 0.8 V transmitted at the transmitter and to 80 mV for 4-PAM as well. However, considering the reference voltage to determine correct data at the receiver, the difference between the reference voltage and the received data voltage level was 40 mV for 4-PAM. Therefore, the voltage margin for

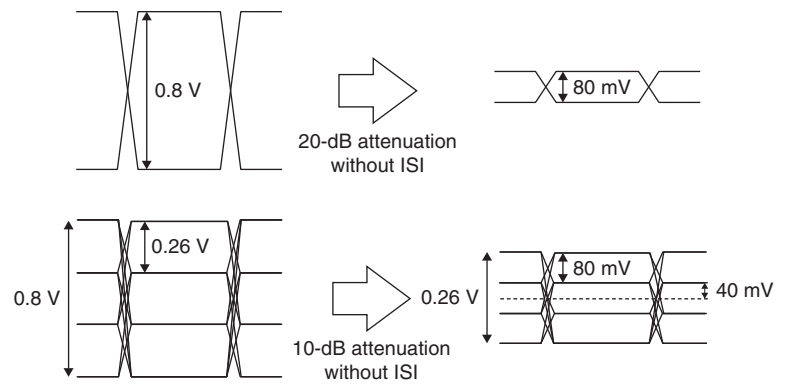

Figure 13: Signal for NRZ and 4-PAM received through channel with attenuation

Figure 14: Transmission medium performances

4-PAM was approximately one-half that for NRZ. This comparison indicates that a higher SNR is required for a 4-PAM receiver than for an NRZ receiver.

CHANNEL PERFORMANCE LIMITATIONS AND SIGNALING COMPARISONS

Examples of channel characteristics of a PCB using a material with a low dielectric constant (low k) are shown in Figure 14. Signal attenuation increases with medium length and frequency. In general, signal attenuation is proportional to medium length and data speed. For example, at a frequency of 5 GHz and for a channel length of 25 cm, the channel loss is approximately -6 dB. It increases to -12 dB for a channel length of 50 cm and to -18 dB for one of 75 cm. The channel loss reaches -18 dB at 10 GHz for a channel length of 25 cm and exceeds -35 dB for one of 75 cm. When the transmission channel has loss, the transmitted data swing either decreases or is attenuated, and the voltage margin required to detect correct data at the receiver is reduced. When the loss becomes larger, the output no longer swings fully. The time-domain effect of the frequency-dependent attenuation is shown in Figure 15. A single square pulse is fed into the 25-cm PCB. The attenuation of the input pulse reduces the signal amplitude

Figure 15: Intersymbol interference (ISI)

by more than 50 percent. The lower frequency attenuation produces the signal's long settling tail. As a result, the values of the previously transmitted bits affect the current bit's waveform. This interference, called *intersymbol interference* (ISI), reduces the transmitted signal's timing and voltage margins. The total effect on transmitted random data is a significant closure of the resulting data eye. The effect of ISI is greater for high-speed and long-distance transmission. Therefore, this ISI hinders efforts to improve the data speed and transmission length.

The way to achieve higher data speed, even with a large loss channel, is to compensate for the frequency dependence of the channel transfer function. An equalizer is widely used to do this. The pre-emphasis technique as one type of equalizer as shown in Figure 16. The pre-emphasis

Figure 16: Equalization by pre-emphasis

Figure 17: (a) Transfer function and (b) single-bit response for 2-PAM (NRZ) signaling

Figure 18: Transfer function (a) and single bit response (b) for 4-PAM signaling

transfer function is set to the inverse of the channel transfer function. As a result, the total transfer function with the channel and the pre-emphasis becomes flat up to the transmitted data frequency, and ISI is compensated.

Figure 17a shows an example of a transfer function, and Figure 17b shows the single bit response for 2-PAM (NRZ) signaling. Without channel equalization, frequency-dependent channel loss causes ISI, which results in the data received at each sampling timing having not only values of 0 or 1 but also intermediate values (nonzero ISI). As a result, binary input data cannot be successfully restored. Channel equalization assures Nyquist-rate bandwidth in the frequency domain—that is, zero ISI in the time domain. This zero ISI means that binary input data can be successfully obtained as binary output data.

Figure 18a shows the transfer function and Figure 18b the single-bit response for 4-PAM signaling. The 4-PAM coding makes it possible to halve the symbol rate. Therefore, channel equalization only has to ensure one-half the Nyquist-frequency bandwidth of 2-PAM to achieve zero ISI. Moreover, the signal amplitude is still kept larger than that of 2-PAM because the effect of channel loss is smaller than in 2-PAM.

However, 4-PAM results in increased sensitivity to cross talk and reflection because the 4-PAM signal includes a maximum transition, which causes proportional cross talk, whereas the data eye amplitude is one-third of the maximum transition.

In response to this situation, *duobinary signaling* has been developed. This type of partial response signaling can be helpful in reducing the required maximum frequency on the channel because it allows for a controlled amount of ISI to be removed afterward. In duobinary signaling, channel loss and equalization combine to produce ISI. An eye diagram of duobinary signaling is shown in Figure 19.

Figure 19: Eye diagram for duobinary signaling

The transfer function and single bit response for duobinary signaling are shown in Figure 20. The transfer function of duobinary is expressed as the z -function $1 + z^{-1}$. Received data are produced by adding current input data and previous input data. Therefore, the transfer function results in binary input data being output as a duobinary three-level signal: $1 + (1) = 2$, $1 + (0)/0 + (1) = 1$, $0 + (0) = 0$, where the value inside each set of parentheses denotes a preceding data bit. Because transmitted data are binary, the data output at the transmitter has to operate at the same speed as that of 2-PAM, and the data received timing is also the same as 2-PAM. However, the Nyquist frequency of duobinary signaling through the channel is smaller than that of 2-PAM. Therefore, the data speed on the transmission channel is eased. Recent LSIs can operate at high speed because of improvements in device performance. However, the transmission channel performance cannot be improved in a similar manner to the device performance improvements. Therefore, reducing the Nyquist frequency

Figure 20: (a) Transfer function and (b) single-bit response for duobinary signaling

Figure 21: Comparison of transfer functions for 2-PAM, 4-PAM, and duobinary signaling schemes

of data through the channel is an effective way to achieve high-speed data transmission.

The data eye amplitudes of 2-PAM, 4-PAM, and duobinary signals can be compared by using the channel loss value at a corresponding Nyquist frequency: f_{nyq} (2-PAM), $f_{nyq}/2$ (4-PAM), and $2f_{nyq}/3$ (duobinary), where f_{nyq} is one-half the symbol rate of 2-PAM. Although duobinary is not a type of Nyquist signaling but a partial response signaling, here the Nyquist frequency of duobinary signaling is defined to compare its characteristics with those of the other signaling types. The Nyquist frequency value was determined from the sampling frequency at which the original waveform can be recovered by the optimum duobinary single bit response with a 1.5-Tsymbol transition time, where Tsymbol is the symbol interval for 2-PAM/duobinary.

Each relationship between Nyquist frequency and received data eye amplitude is calculated from theoretical transfer curves for 2/4-PAM (cosine roll-off) and duobinary ($1 + z^{-1}$). Those for these three types of signaling are compared in Figure 21. The eye amplitude of the 2-PAM signal is 2.1 dB above the gain at f_{nyq} . The eye amplitude of the 4-PAM signal is 7.4 dB below the gain at $f_{nyq}/2$ because of four-level signaling. In contrast, the eye amplitude of the duobinary signal with three levels is only 1.6 dB below the gain at $2f_{nyq}/3$. This is because although the 4-PAM signal includes the maximum transition between the lowest and highest levels, the duobinary signal only includes transitions between adjacent levels. That is why duobinary

signaling has better immunity to cross talk and reflection than does 4-PAM, which is proportional to the maximum transition.

At each Nyquist frequency, when the difference in channel loss between duobinary and 2-PAM is larger than 3.7 dB, the duobinary eye amplitude will be larger than that of 2-PAM. In the same way, when the difference between duobinary and 4-PAM is less than 5.8 dB, the duobinary eye amplitude will be larger than that of 4-PAM. When the difference is larger than 5.8 dB, on the other hand, the duobinary eye amplitude will be smaller than that of 4-PAM. Regarding the comparison between 2-PAM and 4-PAM, when the difference in channel loss between 2-PAM and 4-PAM is larger than 9.5 dB, the 4-PAM eye amplitude will be larger than that of 2-PAM. To summarize the relationship between channel loss and received data eye amplitude of these three signaling types, the 4-PAM data eye is larger for a large channel loss and the 2-PAM eye is larger for a small channel loss.

One example of the comparison is given in Figure 22, which shows the eye amplitudes of 2-PAM, 4-PAM, and duobinary calculated using previous analyses and actual channel loss values at each Nyquist frequency. The effective data rate was set at 12-Gbps for all types of signaling. This figure indicates that 2-PAM has a larger eye amplitude than 4-PAM for a short channel length. This is because the channel loss is small for a short channel length, so the loss difference between the Nyquist frequencies of 2-PAM and 4-PAM is less than 9.5 dB. In contrast, for a long

Figure 22: Comparison of transmitted data eye amplitudes for 2-PAM, 4-PAM, and duobinary signaling schemes with 12-Gbps data rate and low- k PCB

channel length, 4-PAM has a larger amplitude than 2-PAM because the loss is large enough, having a loss difference larger than 9.5 dB. Although duobinary always has a larger eye amplitude than 2-PAM and 4-PAM for channel lengths up to 75 cm according to this estimation, 4-PAM will be more effective than duobinary for longer length or with larger channel loss.

Figure 23 shows the results of measurements made through low- k PCB traces with lengths of (a) 75 cm, (b) 50 cm, and (c) 25 cm. The one on the left of Figure 23

is for 2-PAM signaling, whose eye opening indicates horizontal ISI caused by a steep roll-off. The one on the right of Figure 23a is for duobinary signaling and shows a 3.5-dB larger eye amplitude and 1.5 times larger eye width. Figures 23b and 23c are eye diagrams more than 50- and 25-cm traces of the same material. The eye openings of the 2-PAM and duobinary are comparable to that of the 50-cm trace. When the high-frequency loss of the trace is relatively small, as in a 25-cm trace, 2-PAM signaling has a larger eye opening than duobinary signaling.

To summarize the signaling comparison, the dependence of the maximum transmission length on data rate is shown in Figure 24. This was estimated using an FR4 PCB trace. Equalization techniques, such as pre-emphasis and receiver equalization, improve the transmission length about two times. Several signaling techniques (for example, PAM or duobinary signaling) improve the transmission length even more, and it reaches 50 cm at 10 Gbps. When a longer length is required, better channel performance will be necessary, and noise immunity techniques are also essential to achieve high-speed and long-distance transmission. Moreover, optical transmission is one candidate for achieving a length longer than 1 m and a transmission speed higher than 10 Gbps.

APPLICATIONS

This section discusses applications that have been determined to be suitable for PAM transmission, including duobinary transmission. Serial communication applications and their required bandwidths are shown in Figure 25. Serial communication is widely used, regardless of the

Figure 23: Comparison of measurement data eyes of 2-PAM and duobinary with 12-Gbps data rate

Figure 24: Techniques for high-speed and long-distance transmission

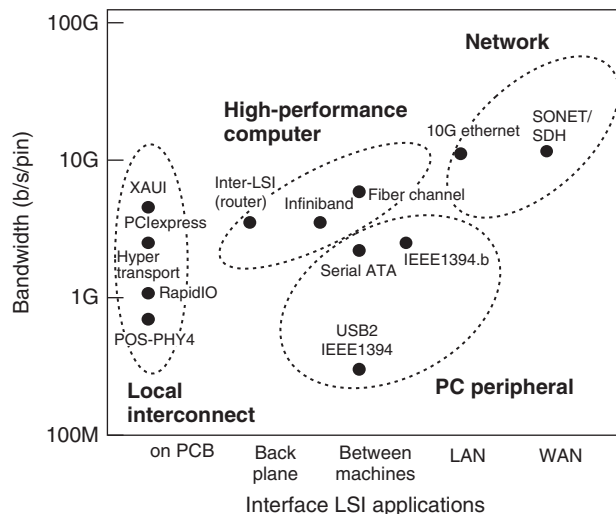

Figure 25: Interface applications

channel length or application. The transmission rate of serial communication has been increased to beyond the Gigahertz range. From the perspective of the transfer function, PAM is effective for increasing the total bandwidth of transmitted data while keeping the data rate low when the frequency dependence of channel loss is high. Applications using PAM therefore fall into two types: (1) transmission with a large loss and (2) transmission with a fixed operating speed because of some limitation imposed on device performance.

Large-loss transmission means long-distance communication, such as in the backplane, between machines, or in a LAN, as shown in Figure 25. Regarding device limitation, it is effective to achieve a higher data bandwidth with a low-speed device in the early stage after a product has been launched on the market. Its effect, however, declines as process technology is improved. Therefore, applications using the PAM technique are focused on those communications

over a long transmission length or large frequency-dependent loss in channels. For example, the 100BASE-T2 and 1000BASE-T standards for Ethernet adopt 5-PAM signaling, and several proposals for 10GBASE-T have been considered, including twelve-, ten-, and eight-level PAM (12-PAM, 10-PAM, and 8-PAM).

To achieve high-speed circuit operation, let us consider the relationship between the maximum operating frequency of circuits and the gate length. The maximum frequency is inversely proportional to the gate length or design rule, as shown in Figure 5. By simply extrapolating the fitting line, we can see that we should be able to reach 5-Gbps operation with 0.1- μm CMOS technology if we use a single architecture, which operates with the same frequency clock signal as the transmitted data rate. A more radical design is obviously needed to overcome the conventional circuit limitations and further improve the circuit performance. The parallel architecture and circuit technique have achieved twice the performance of the conventional design, as shown in Figure 5. This circuit technique is independent of the design rule, so it is always effective at doubling the processing speed. The maximum transmitted data rate, for example, has exceeded 10 Gbps with 90-nm CMOS. Moreover, it has reached more than 20 Gbps with 4-PAM transmission techniques using 90-nm technology. Oversampling, in which sophisticated decision control logic can operate at a lower frequency, with multi-phase clocks is also an effective approach for getting the most out of CMOS characteristics. For example, 4-Gbps operation can be achieved with 500-MHz, eight-phase clock signals by using 0.5- μm CMOS technology, and 12-Gbps operation using 3-GHz and four phases. These architectures for high-speed operation with lower-speed devices are supported by the high level of integration of CMOS technology compared with non-CMOS technology.

Another important point for achieving high-data bandwidth transmission is sophisticated equalization techniques, such as the pre-emphasis, liner equalizer, and the decision feedback equalizer. These approaches make it possible to increase the transmission length with high-speed data on large-loss media. They are also supported by the high level of integration of CMOS.

On the other hand, we have to solve several design issues on the road to high operating speed LSIs. As supply voltage and design rules are reduced in accordance with device scaling, *signal integrity* problems become serious. One major drawback of CMOS push-pull operation is the large switching noise induced by sudden current flows on the power and ground lines. Switching noise on the power and ground lines, for example, can reach approximately 100 mV. The digital switching noise could cause delay time variations or errors in logical operation. The silicon substrate itself is another source of digital switching noise. Substrate noise, for example, reaches some 50 mV. Analog circuits, such as the PLL and preamplifier, are highly sensitive to this noise. These types of switching noise degrade transmission data because the noise degrades the accuracy of the clock signal, which determines the transmission data timing and directly affects the data waveforms.

To increase the data bandwidth or channel length by using the PAM, we need to apply noise immunity techniques because the received data are degraded or

attenuated when the receiver circuit noise becomes larger as the operating speed increases. Moreover, PAM signaling has multiple data eyes at the same received timing. Therefore, the SNR of PAM signaling is smaller than that of 2-PAM or NRZ signaling.

Using an optical fiber as the channel is an effective way to increase the channel length. In a case such as this, the output buffer is replaced with a laser driver, and the input buffer is a photo detector. The application of PAM technique to optical communications presents a new problem: The linearity of the laser driver and the photo detector emerges as a new obstacle to surmount.

CONCLUSION

This chapter presented a brief review of recent research on high-speed communication technology. Pulse amplitude modulation was presented as one solution for increasing the amount of data transmitted while simultaneously maintaining a low data rate. PAM effectively increases the data-transmission bandwidth through large-loss transmission channels or in long-distance communication. The development of a PAM transceiver involved surmounting several significant obstacles. One was the challenge of eliminating the trade-off between higher data throughput and improved signal-to-noise ratio for received data. Another was achieving a sufficient voltage margin for the attenuated transmitted signal.

GLOSSARY

- Duobinary:** A type of partial response signaling. The transmitted pulse is based on the sum of last two bits.
- Eye diagram:** Diagram used to visualize the waveforms that are used to send multiple bits.
- Intersymbol interference (ISI):** Distortion of received signal; the previously transmitted bits affect the current bit's waveform.
- Non-return to zero (NRZ):** Binary code with two levels.
- Nyquist frequency:** The highest frequency that can be coded at a given sampling rate in order to be able to fully reconstruct the signal. It is equal to one-half the signal's sampling frequency.
- Pre-emphasis:** Based on FIR filters, to be performed to boost high frequency signal content on the transmitter side.
- Reference voltage:** The voltage to determine received data.

INTRODUCTION

Angle modulation denotes the types of modulations in which the angle of a carrier is varied according to the amplitude of the modulating baseband signal. In this type of modulation, the amplitude of the carrier is kept at a constant value. There are several ways in which the phase of the carrier— $\theta(t)$ —can be changed in accordance with the modulating signal. The two classes of angle modulation are frequency modulation and phase modulation.

PRINCIPLES OF FREQUENCY MODULATION

Frequency modulation (FM) is based on changing the instantaneous frequency of a carrier according to the amplitude of the baseband modulating signal. Conceptually, FM can be implemented by a modulating signal that changes with time placed at the input of a *voltage-controlled oscillator* (VCO). The frequency at the output of the VCO can be written as:

$$f_i(t) = f_c + k_0 v_m(t) \quad (1)$$

in which $f_i(t)$ is the instantaneous output frequency of the VCO, f_c is the output frequency of the VCO in the absence of a modulating signal, $v_m(t)$ is the modulating signal, and k_0 is the VCO constant expressed in Hz/V.

Assuming that when $v_m = 0$ then $f_i(t) = f_c$, Equation 1 can be rewritten as:

$$f_i(t) = f_c + \Delta f_c \quad (2)$$

with $\Delta f_c = k_0 v_m(t)$.

Therefore, the variations in f_c follow exactly the variations in the amplitude of the modulating signal.

An angle-modulated signal can be expressed as:

$$s(t) = A \cos \theta(t) \quad (3)$$

With $\theta(t)$ being the time-varying angle displacement of the signal. Equation 3 can be rewritten as:

$$s(t) = A \cos (\omega t + \Phi) \quad (4)$$

In Equation 4, the angle variations can be the result of ωt or Φ . When Φ is changed depending on the modulating signal, the resulting complex signal is called *phase modulation* and will be studied in detail later in this chapter. When the ωt angle is changed depending on the modulating signal while keeping Φ constant, the resulting signal is called *frequency modulation*.

Modulation Index

The *modulation index* is a parameter that measures the relative amounts of information-to-carrier amplitude in the resulting modulated signal and is specifically used to determine spectral power distribution. Assuming for simplicity a sinusoid as the modulating signal, the modulation index is defined as the peak phase-angle deviation of the carrier:

To find the instantaneous frequency of a FM signal, we need to consider the fundamental relationship between frequency and phase. The *angular frequency* (ω) of a signal can be written as:

$$\omega = \frac{d\theta}{dt} \quad (5)$$

Therefore, using the relationship between linear and angular frequency in equation 1, we can write:

$$\frac{d\theta}{dt} = 2\pi f_c + 2\pi k_0 v_m(t) \quad (6)$$

Integrating this yields:

$$\theta(t) = \int_{-\infty}^t 2\pi f_c dt + \int_{-\infty}^t 2\pi k_0 v_m(t) dt \quad (7)$$

The first integral can be evaluated immediately, therefore:

$$\theta(t) = 2\pi f_c t + \theta_0 + \int_{-\infty}^t 2\pi k_0 v_m(t) dt \quad (8)$$

with θ_0 being the arbitrary phase at $t = 0$.

This then leads to the general form of the FM equation:

$$S_{FM}(t) = A \cos \left[2\pi f_c t + 2\pi k_0 \int_{-\infty}^t 2\pi k_0 v_m(\lambda) d\lambda \right] \quad (9)$$

Equation 8 shows that, in general, the instantaneous phase of a FM signal is dependent on the type of modulating signal. Again assuming for simplicity a sinusoidal modulating signal such as $v_m(t) = V_{pk} \cos(2\pi f_m t)$ for use in Equation 8, and assuming that the initial phases are zero, it is then possible to write:

$$\theta(t) = 2\pi f_c t + \left(\frac{k_0 V_{pk}}{f_m} \right) \sin 2\pi f_m t \quad (10)$$

Therefore,

$$\theta(t) = 2\pi f_c t + \left(\frac{\Delta f_c(pk)}{f_m} \right) \sin 2\pi f_m t \quad (11)$$

Substitution of Equation 11 in Equation 3 gives the equation that mathematically describes the FM signal:

$$S_{FM}(t) = A \cos(2\pi f_c t + m_f \sin 2\pi f_m t) \quad (12)$$

$$\text{with } m_f = \left(\frac{\Delta f_c(pk)}{f_m} \right) \quad (13)$$

The parameter described in Equation 13, m_f is the *modulation index* for a sinusoidal modulating signal expressed in radians. Equation 12 shows that m_f is the peak of the phase-angle signal, which also changes with time following a sine form.

Narrowband Frequency Modulation

The frequency spectrum of a FM signal depends on both the modulating signal and the modulation index. Because the modulated FM signal is a nonlinear function of the modulating signal, its spectrum must be evaluated on a case-by-case basis. It has been shown that for a

sinusoidal modulating signal like those considered here, the amplitudes of the spectral components are given by Bessel functions of the modulation index, m_f . However, in special cases—for example, in those cases in which the modulation index is small, or *narrowband FM* (NBFM)—it is possible to simplify the resulting function. Assuming a sine-modulating signal and after some trigonometric manipulation, Equation 11 can be rewritten as:

$$s_{FM}(t) = A(\cos(m_f \sin \omega_m t) \cos \omega_c t) - A(\sin(m_f \sin \omega_m t) \sin \omega_c t) \quad (14)$$

In those cases with small modulation indexes, we can do the following approximations:

$$\cos(m_f \sin \omega_m t) \approx 1 \text{ and } \sin(m_f \sin \omega_m t) \approx m_f \sin \omega_m t$$

Therefore, the FM signal described in Equation 13, assuming small modulation indexes, can be approximated as:

$$s_{FM}(t) \approx A(\cos \omega_c t) - A(m_f \sin \omega_m t) \sin \omega_c t \quad (15)$$

The first term in Equation 15 is a carrier signal, while the second term is the sidebands. Focusing now on the sidebands term, we can rewrite it as:

$$A(m_f \sin \omega_m t) \sin \omega_c t = \left(\frac{A m_f}{2} \right) \cos(\omega_c - \omega_m)t - \left(\frac{A m_f}{2} \right) \cos(\omega_c + \omega_m)t \quad (16)$$

Equations 15 and 16 show that the spectrum of a NBFM consists of a carrier with constant amplitude and two sidebands with a form similar to double sideband with suppressed carrier. Its peak amplitude depends on the amplitude of the modulating signal as well as the modulation index. Therefore, the bandwidth required to transmit the NBFM signal includes the carrier and a single set of sidebands separated in $\pm \omega_m$ from the carrier frequency. The validity of this conclusion—and therefore the assumption of working with a NBFM signal—is better as the value of m_f is lower, but in any case it cannot exceed approximately 0.25 for the approximation to remain valid.

Wideband Frequency Modulation

When the previous approximation cannot be used because of the higher value of the modulation index, Equation 13 describes the time dependence of the FM signal. From this equation, it is possible to observe how the amplitude variations of the carrier components become quite complicated. In fact, the amplitudes of the carrier at the different frequencies cannot be evaluated in a closed form. The peak amplitude of the carrier for a FM signal with modulation index m_f is given by the Bessel function of

first kind of order zero as $V_c pk = A J_0(m_f)$. In general, the amplitude of any sideband is given as

$$V_n pk = A J_n(m_f) \quad (17)$$

where A is the amplitude of the modulating signal and $J_n(m_f)$ is the Bessel function of first kind of order n that can be easily found in the tables elsewhere.

An important implication from these equations is that the spectrum of the FM signal has theoretically infinite components. In a practical manner, $J_n(m_f)$ tends to zero for values of n large enough for any given modulation index, so for practical purposes we can consider the FM signal as being limited in bandwidth. One criterion is to limit the value of sidebands with amplitude higher than 1 percent of the amplitude of the unmodulated carrier (Proakis and Salehi 1994). Bessel functions decay more slowly with increasing values of the modulation index m_f . Therefore, FM signals with larger modulation indexes have a much wider power spectral as it could be qualitatively suggested by the definition of modulation index.

We can also use this approach to evaluate the bandwidth of the NBFM signal. By considering the Bessel functions for a modulation index of 0.25, it is possible to see that only the first-order sidebands have amplitudes that exceed 1 percent of the unmodulated carrier. This in turn results in a power spectrum that contains the carrier and a single sideband at each side as it was discovered in the previous section using a different approximation.

A somewhat alternative and empirical criteria to establish the bandwidth of the FM signal for practical purposes without resorting to evaluating the Bessel functions is known as *Carson's rule*. Carson's rule states that for small values of the modulation index the spectrum of the FM signal contains the carrier frequency and one pair of sideband frequencies separated in f_m Hz from the carrier at frequency f_c . Carson's rule also states that, for larger values of the modulation index, the bandwidth of the FM signal can be found as:

$$B = 2(m_f + 1)f_m \quad (18)$$

Equation 18 clearly shows how increasing values of the modulation index will result in higher values of spectral bandwidth.

MODULATION METHODS FOR FREQUENCY MODULATION

There are two basic methodologies for generating a FM signal: direct method and indirect method. In the *direct method*, the frequency of a carrier is directly varied according to the amplitude of the modulating signal. In the *indirect method*, a balanced modulator generates a NBFM signal; by further multiplying in frequency, it is possible to achieve the desired frequency carrier and frequency deviation. These two methods are further developed in the upcoming sections.

Modulation Techniques for FM

The most basic approach to generating a FM signal by the direct method is by using a voltage controlled oscillator. The VCO is followed by a buffer amplifier and finally amplified to its final output power by the appropriate power amplifiers. Because of the nonlinearity of the FM signal, it is possible to use nonlinear amplifiers operating near their saturation point and therefore increase the efficiency of the whole system.

However, because VCOs are notorious for exhibiting poor frequency stability, it is necessary to introduce additional circuitry to solve this problem. One of the most common approaches is to use a feedback circuit that stabilizes the frequency of the carrier. Another method is to generate the FM signal from a phase-modulation signal as we will discuss later in this chapter.

For practical applications, however, the best approach is to use one of the several commercial integrated circuits designed and optimized for these applications. For example, the family of integrated circuits MAX2605 to MAX2609 from Maxim are a series of highly stable VCOs with central frequencies that range from 45 MHz to 650 MHz. Application note 1869 from the same manufacturer shows how to use these circuits to generate low-power FM signals in the commercial broadcasting band (Maxim Semiconductor 2003). National Semiconductor has also several solutions to generate FM signals with the traditional LM566 and LM565 pair of chips (National Semiconductor 1975). In the higher frequency ranges, the TRF6900 from Texas Instruments provides in a single chip a solution to NBFM and FSK transmission in the 900-MHz ISM band (Texas Instruments 2005). Given the recent development of digital circuits and, in particular, *digital signal processing* (DSP), it is also possible to generate high-quality FM signals using all-digital circuitry. The advantages of not requiring periodic recalibration or it drifts with temperature or power supply variations make it advantageous even with its initial increased complexity (Analog Devices undated). Although this list of options is not exhaustive, it indicates the practical directions to follow at the time of implementing a system to generate FM signals.

Demodulation Techniques for FM

The demodulation circuits for FM signals are based on the *superheterodyne principle*, similar to those for *amplitude-modulated* (AM) signals. However, because in FM signals there is no information in the amplitude of the carrier, it is not necessary to use automatic gain control circuits.

In general, a FM demodulator produces an output voltage that is proportional to the instantaneous frequency of the signal at its input. Using an approach similar to the one used to develop equation 1, we can develop the equation for the FM demodulator:

$$v_o(t) = k_d f(t) \quad (19)$$

in which $f(t)$ is the instantaneous input frequency for the FM demodulator, $v_o(t)$ is the output demodulated signal, and k_d is the gain of the demodulator, expressed in V/Hz.

Figure 1: Basic structure of a PLL

There are three possible ways of implementing Equation 19: (1) a demodulator based on *phase-locked loops* (PLL), (2) demodulators based on slope detection (also known as *FM discriminators*), and (3) quadrature detectors.

Figure 1 shows the basic structure of a FM demodulator based on a PLL. If we call $f_c(t)$ the FM signal at the input of the demodulator, we can write:

$$f_c(t) = k_o v_m(t) \quad (20)$$

where k_o is the constant of the VCO for the modulator and $v_m(t)$ is the modulating signal.

In the circuit of Figure 1, the output of the VCO (k_d) is compared with the input signal using a phase comparator, producing an output voltage that is proportional to the phase difference. The phase difference signal is in turn fed back into the VCO to control the output frequency. Therefore, changes between the frequency of the FM signal and the signal generated by the VCO are converted into changes in the amplitude of the output signal, V_o .

The slope detection demodulation method is based on taking the time derivative (slope) of the FM signal and following it with envelope detection. We can write the expression for the FM signal at the input of the demodulator as:

$$v_{FM}(t) = A \cos[2\pi f_c t + \theta(t)]$$

with $\theta(t)$ given by Equation 8 as $\theta(t) = 2\pi f_c t + \theta_0 + \int 2\pi k_o v_m(t) dt$.

After the FM signal $v_{FM}(t)$ is passed through a differentiator—a filter with transfer function has a gain that increases linearly with frequency—the signal at the output of the differentiator is:

$$v_{fil} = -A \left[2\pi f_c t + \frac{d\theta(t)}{dt} \right] \sin(2\pi f_c t + \theta(t)) \quad (21)$$

After the signal v_{fil} is passed through an envelope detector, its output is:

$$\begin{aligned} v_o(t) &= -A \left[2\pi f_c t + \frac{d}{dt} \theta(t) \right] \\ &= A[2\pi f_c t + 2\pi k_o v_m(t)] \end{aligned} \quad (22)$$

The DC value contained in Equation 22 can be easily eliminated by filtering, resulting in an output voltage that is proportional to the original modulating signal.

Quadrature detection is another method for demodulating the FM signal. It is based on a network that shifts the phase of the incoming FM signal by an amount proportional to its instantaneous frequency, followed by a phase detector between the original FM signal and the signal at the output of the network. With this approach, the output voltage is proportional to the instantaneous frequency of the incoming FM signal. This type of FM demodulation is therefore based on a frequency-to-amplitude conversion.

Similarly to FM modulator circuits, it is possible to find high-quality FM demodulators based on different integrated circuits. For example, the CD4046B from Texas Instruments is an extremely versatile PLL that has been widely used for demodulation purposes. Other integrated circuits, such as the TRF6900 from Texas Instruments, are transceivers that can be used to implement the transmitter and receiver for a digital FM system (Texas Instruments 2003). The AD8348 integrated circuit from Analog Devices is a demodulator based on quadrature detection that can work in the frequency range from 50 MHz to 1000 MHz, thus making it extremely flexible for a large number of applications. Another chip from Analog Devices is the AD650 chip that is a voltage-to-frequency and frequency-to-voltage converter, making it suitable to FM generation and detection, although in this case the frequency range is limited to 1 MHz.

PERFORMANCE OF THE FREQUENCY-MODULATED SIGNAL

Because FM is a nonlinear modulation, the analysis of noisy FM systems can be quite complicated, so some approximations and generalizations need to be made. At the same time, this nonlinearity proves to be critical to make FM signals more robust than linearly modulated signals. We need to remember that a FM signal carries the information in its frequency—that is, in the sequence of its zero-crossings. Because noise is normally additive, it affects the amplitude of the FM signal but has a much lower effect in changing its zero crossings. It is then usual for receivers to clip or limit the amplitude of the FM signal before frequency detection in order to provide a constant amplitude signal at its input.

Noise in the Frequency Modulated Signal

Assuming the previous FM signal $v_{FM}(t) = A \cos[2\pi f_c t + \theta(t)]$ with $\theta(t)$ given by Equation 8, its phasor has a constant amplitude of A volts and an angle of $2\pi\theta(t)$, circling around in the complex plane. The noise is a random process that can be decomposed into its quadrature components:

$$n(t) = x(t) \cos 2\pi f_c t - y(t) \sin 2\pi f_c t \quad (23)$$

where $x(t)$ and $y(t)$ are random processes (Proakis 2001). Figure 2 represents these phasors in the complex plane.

Adding the noise phasor to the FM signal, the resulting signal has a different amplitude and phase. The change in amplitude is irrelevant because no information is

Figure 2: Phasor diagram for noise in the FM signal

contained in the amplitude, so the only important change is in the phase ($\Delta\theta$). As long as the amplitude of the noise does not exceed the value A , the change in phase $\Delta\theta$ will be less than 45 degrees. This situation is not unusual because the amplitude of the noise will normally be lower than the amplitude of the FM signal.

The expression for the resulting signal $r(t)$ can be written as:

$$r(t) = \sqrt{[A + x(t)]^2 + y(t)^2} \cos \left[2\pi f_c t - \tan^{-1} \left(\frac{y(t)}{A + x(t)} \right) \right] \quad (24)$$

When the resulting signal is demodulated, the limiter will keep its amplitude constant, therefore its output will only respond to the cosine term. After the limiter, the signal is then passed through the discriminator-envelope detector, resulting in the following signal (Roden 2001):

$$\frac{d\theta}{dt} = \frac{[x(t) + A] \frac{dy}{dt} - y(t) \frac{dx}{dt}}{y(t)^2 + [x(t) + A]^2} \quad (25)$$

With the assumption of a high carrier-to-noise ratio [$A \gg x(t)$ and $ZA \gg y(t)$], Equation 25 can be rewritten as:

$$\frac{d\theta}{dt} \approx \frac{\frac{dy}{dt}}{A} \quad (26)$$

Equation 26 gives the change in the phase angle originated as a result of additive noise.

Noise Capture in the Frequency-Modulated Signal

The previous equations show the improvement in noise performance of the FM detector when the amplitude of

the signal is larger than the amplitude of the noise. If the amplitude of the noise is larger than the amplitude of the signal, the detector locks onto the noise and suppresses the signal. This phenomenon is known as *noise capture* and is commonly seen while listening to a distant FM station in a car as we drive away from the station, noting that it gets to a point in which the station drops out totally and is replaced by static. At this point, the FM receiver has locked onto the noise instead of the signal. This is one of the main drawbacks of FM systems in which the noise performance drops to zero after a certain threshold *signal-to-noise ratio* (SNR). A similar effect occurs when two signals are broadcasted simultaneously: The FM receiver will lock onto the stronger signal and ignore the weaker signal.

Trade-Off between Signal-to-Noise Ratio and Bandwidth for the FM Signal

In the FM signal, the SNR before the detection depends on the bandwidth of the filters in the receiver, the power of the received carrier, and the power of the noise signal. However, the signal-to-noise ratio after the detection process is a function of the maximum frequency of the message (f_m), the modulation index (m_f), and the SNR at the input (Rappaport 1996).

The signal-to-noise ratio at the output of a properly designed FM detector can be written as (Couch 1993):

$$(SNR)_o = 6(m_f + 1)m_f^2 \left(\frac{m(t)}{V_p} \right)^2 (SNR)_i \quad (27)$$

with V_p being the peak voltage of the modulating signal $m(t)$ and m_f , the modulation index. We must take into consideration that Equation 27 is only valid for high carrier-to-noise ratios. The expression of the SNR and the input is given by:

$$(SNR)_i = \frac{A_c^2 / 2}{2N_o(m_f + 1)Bw} \quad (28)$$

where A_c is the amplitude of the carrier, N_o is the noise density (assumed to be white noise), and Bw is the bandwidth of the filter used.

In the simplified case of a modulating sinusoidal signal, $m(t) = A_m \sin \omega_m t$, Equation 27 results in:

$$(SNR)_o = 3(m_f + 1)m_f^2 (SNR)_i \quad (29)$$

Equation 29 clearly shows that by increasing the modulating index m_f for the FM signal, it is possible to increase the signal-to-noise ratio at the output of the demodulator. However, as it was described earlier in the chapter, an increase in m_f results in an increase of the transmission bandwidth. Thus, the increase in $(SNR)_o$ is at the expense of using higher amounts of bandwidth, and therefore the designer of a FM system must carefully analyze signal-to-noise and bandwidth requirements in order to reach

a compromise. From Equation 18, we can see that for large values of m_f , the transmission bandwidth is proportional to the modulation index m_f . Therefore, Equation 29 shows that the SNR at the output of the demodulator increases with the cube of the transmission bandwidth, thus making it an excellent technique for the transmission of fading signals. It can also be shown (Rappaport 1996) that given the same conditions for the carrier and noise values, the detection of FM signals result in much higher values of $(\text{SNR})_o$ than for AM signals. Frequency modulations improve performance through the adjustment of the modulation index at the transmitter and not the transmitted power. This is not the case of AM signals because, being a linear modulation technique, it does not trade bandwidth for SNR.

All of the previous considerations are valid only if the SNR at the input of the detector exceeds the threshold for which the detector locks onto the signal and not onto the noise. For the majority of detectors in practical applications, this threshold for $(\text{SNR})_i$ has an approximate value of 10 dB, although with some additional circuitry it can be improved down to 6 dB.

FREQUENCY MODULATION FOR DIGITAL SIGNALS: FREQUENCY SHIFT KEYING

When the modulating signal is a digital signal instead of an analog signal, the resulting frequency-modulating signal receives its own specific name: *frequency shift keying* (FSK). Contrary to analog FM in which the instantaneous frequency of the carrier can have any value within its maximum deviation frequency, in FSK the number of possible carrier instantaneous frequencies is limited to a given subset. The most basic case, in which only two instantaneous frequencies can be transmitted, is called *binary FSK* (BFSK). For more complex systems, and to increase the bit transmission rate, the number of possible instantaneous carrier frequencies is higher, normally a power of 2. This situation is called *M-ary FSK*, where M represents the total number of different possible instantaneous frequencies. These two approaches are explained in further detail in the following subsections.

Binary Frequency Shift Keying

Binary frequency shift keying transmits two different frequencies (f_0 and f_1) to represent a logic 0 or a logic 1 following an established protocol. The transmission of BFSK can be easily accomplished by having two oscillators operating at frequencies f_0 and f_1 , followed by a switch that will select one or the other based on the digital input. Although this is a simple procedure, it results in discontinuities of the carrier frequency at the time of switching. This in turn results in additional high-frequency components, thus needing a much wider bandwidth transmission.

BFSK can also be generated using the VCO approach in a manner similar to analog signals. Because the digital modulating signal will never have a zero rise or settling time, this digital modulation is in fact an analog modulation with a very short transition time. In this case, the

carrier has a continuous and smooth transition, therefore guaranteeing phase continuity and requiring a narrower spectrum for transmission. This method is known as *continuous phase frequency shift keying* (CPFSK). Although it has been introduced here for BFSK, it can also be readily applied for multilevel modulation systems.

Similar to analog FM, the spectrum for BFSK signals is complex and strongly dependent on factors such as the separation between the transmitted frequencies f_0 and f_1 and the symbol rate. Two special cases deserve deeper study: When the spacing between the two frequencies is made exactly equal to the symbol rate, the resulting FSK modulation is called *Sunde's FSK*. The power spectral density in this case can be written as (Bateman 1999):

$$G(f)_{\text{Sunde's FSK}} = \frac{1}{4} \left[\delta \left(f - 0.5 \frac{1}{T_b} \right) + \delta \left(f + 0.5 \frac{1}{T_b} \right) \right] + \frac{4T_b}{\pi^2} \left[\frac{\cos(\pi f T_b)}{4f^2 T_b^2 - 1} \right]^2 \quad (30)$$

with T_b being the symbol rate.

Equation 30 shows that the spectrum for Sunde's FSK contains two discrete spectral lines at the two symbol frequencies—given by the first component of the equation—plus a broader spectral band given by the last component of the equation.

Minimum shift keying (MSK) is a type of *continuous phase modulation* (CPM). Its power spectral density is (Bateman 1999):

$$G_{\text{MSK}}(f) = \frac{16T_b}{\pi^2} \left[\frac{\cos(2\pi f T_b)}{16f^2 T_b^2 - 1} \right] \quad (31)$$

Comparing Equations 29 and 30, we can easily see that the power spectral density for MSK is similar to the one for Sunde's FSK without the energy at the two discrete frequencies. Moreover, the main lobe for MSK is much narrower because it can be expected from the narrower frequency separation between symbols. However, it is also important to note the advantage of the pronounced spectral lines that appear on Sunde's FSK to lock on and demodulate the FSK signal.

In general, the detection of BFSK signals can be achieved by means of either noncoherent or coherent detection. *Noncoherent detection* is based on simultaneously injecting the BFSK into two bandpass filters, each one tuned to the transmitted frequencies, f_0 or f_1 , as shown in Figure 3. The output of each filter is connected to an envelope detector, and their outputs are combined to reconstruct the baseband modulating signal.

Alternatively, noncoherent FSK detection can be achieved by applying the FSK signal to the input of a PLL. The output of the internal VCO will switch between frequencies following the signal at the output of the PLL, thus locking onto the incoming FSK signal so that the output changes between the logic levels of 0 and 1, depending on the frequency of the incoming signal.

The coherent detection of BFSK signals can be achieved with the approach outlined in Figure 4.

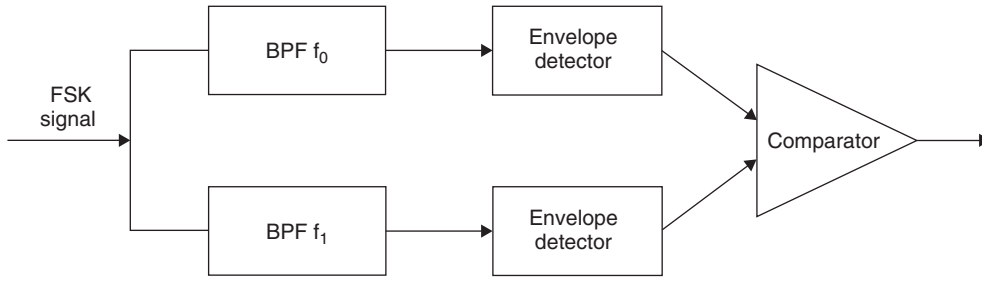

Figure 3: Noncoherent FSK detection

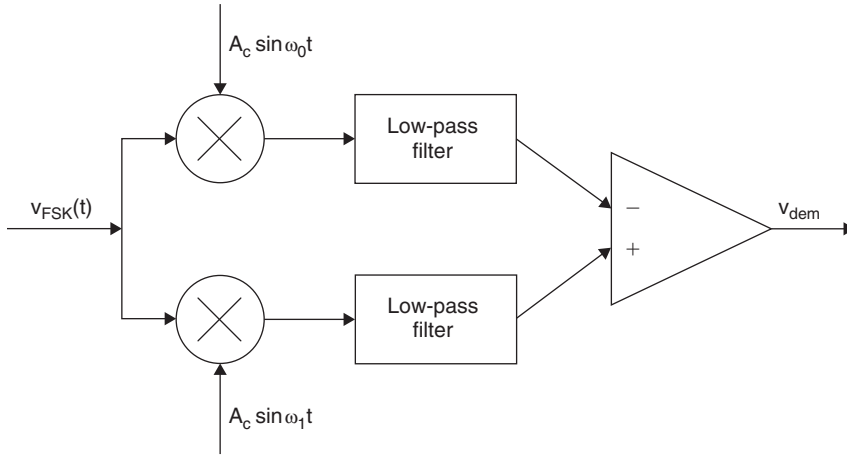

Figure 4: Coherent FSK detection

This approach requires the generation of two carriers with the same exact frequencies and phases as those used at the transmitter. Let us assume in the following analysis that the instantaneous frequency of the carrier at this moment is ω_1 —that is, $v_{FSK} = A \sin \omega_1 t$. The output of the first mixer, the generator with a carrier at ω_0 is:

$$\begin{aligned} v_1(t) &= A A_c \sin(\omega_1 t) \sin(\omega_0 t) \\ &= \frac{A A_c}{2} \cos(\omega_1 - \omega_0)t - \frac{A A_c}{2} \cos(\omega_1 + \omega_0)t \end{aligned} \quad (32)$$

The output of the lower mixer, the generator with a carrier at ω_1 is:

$$v_2(t) = A A_c \sin^2(\omega_1 t) = \frac{A A_c}{2} (1 - \cos(2\omega_1 t)) \quad (33)$$

The last term in Equation 32 and the second term in Equation 31 can be easily removed by the low-pass filter. If the first term in Equation 31 falls within the pass band of the low-pass filter, it must be eliminated by a notch filter for the DC value that appears in Equation 33 to be the only input into the comparator. However, the use of the notch filter has limitations because of its long transition process. The resulting DC signal is connected at the input of a comparator that will result in a logic 1 at its output.

A similar sequence of events happens when the instantaneous frequency of the FSK signal is ω_0 . In this case, the DC value will be applied at the other input of the comparator. Therefore, the output of the comparator is a logic 0.

The *bit error rate* (BER) performance for BFSK modulations depends on the type of detection (coherent versus noncoherent) used in the demodulation process. In general, for a given BER, coherent detection requires approximately 3 dB less SNR (specified as energy per bit divided by noise spectral density) than noncoherent demodulation, thus resulting in a more robust type of detection. This advantage is at the cost of increased complexity. In the case of noncoherent detection, the BER can be expressed as (Bateman 1999):

$$BER_{BFSK, Non-Coh} = 0.5 e^{-\frac{0.5 E_b}{N_o}} \quad (34)$$

while for coherent detection, the BER is:

$$BER_{BFSK, Coh} = 0.5 \operatorname{erfc} \left(\sqrt{\frac{E_b}{2 N_o}} \right) \quad (35)$$

where $\operatorname{erfc}(x)$ is the complementary error function of the variable x (the values of which can be easily found in the appropriate mathematical tables) and E_b , the average energy per bit.

There are integrated circuits in the market that perform FSK transmission, reception, or both. The integrated circuit MAX7032 from Maxim is a FSK transceiver with a carrier frequency from 300 MHz to 450 MHz selectable by the user. The MAX7031 is similar, although it can only operate in three fixed frequencies in that range. From the

same manufacturer; the MAX1479 is an ASK/FSK transmitter and the MAX1471 is an ASK/FSK receiver in that specific frequency range. In some cases, it may be necessary to implement the FSK system with a VCO using the approaches outlined in this section. The integrated circuit MAX2754 is a 1.2 GHz VCO with linear modulation input to build the FSK system.

The TRF4903 chip from Texas Instruments is a radio frequency transmitter based on VCO that has been designed to implement FSK systems, while the TRF6900 is a FSK transceiver in the 800-MHz to 900-MHz band (Texas Instruments 2001). The majority of commercial FSK transmitters, receivers, or transceivers are designed for frequency operation in the ISM band. The ADF7901, ADF7011, and ADF7010 from Analog Devices are all FSK transmitters in the ISM band frequency range. In general, when it is necessary to operate in another frequency range, it is possible to do so by using a VCO with the appropriate frequency band.

M-ary Frequency Shift Keying

The demands for higher transmission speed have spurred the development of techniques for transmission of more than just two states. As long as the number of states transmitted is finite, the resulting form of communication is still digital in nature but no longer binary. M-ary transmission designates this type of multisymbol transmission, where M indicates the number of levels used.

M-ary FSK is based on utilizing M-frequencies in a manner similar to BFSK. The key aspect for this type of modulation is the appropriate separation of the frequencies used. If we desire to maintain the same frequency separation for BFSK, we can easily see that M-ary FSK will require a higher transmission bandwidth. On the opposite side, we can squeeze a number of frequencies into the same space utilized by BFSK and improve the transmission bandwidth. However, in this last case, the noise immunity of the M-ary FSK system decreases when compared to the BFSK. By utilizing a specific set of frequencies, it is possible to find the best trade-off between noise immunity and transmission bandwidth. These are known as *orthogonal frequencies* and represent the best choice to increase the noise immunity of the whole system. The set of orthogonal frequencies is given by:

$$f_m = f_c + \frac{m}{2T_s} \quad (36)$$

where f_m represents each one of the orthogonal set of frequencies $m = 1, 2, \dots, M$, f_c is the carrier frequency, and T_s is the period for the symbol rate.

For example, the orthogonal frequencies for an 8-ary FSK system with a symbol rate of 1400 symbols per second and a carrier frequency of 1000 Hz can use the following set: 1000 Hz, 1700 Hz, 2400 Hz, 3100 Hz, 3800 Hz, 4500 Hz, and 5200 Hz with the same starting phase.

A good approach for M-ary FSK detection is to use coherent demodulators similar to the one shown in Figure 4. In this case, we will need M multipliers, each one with an oscillator at one of the frequencies from the orthogonal set, thus increasing the complexity of the system.

As easily expected, as the number of symbol states (M) increase, the BER rate improves, albeit at the expense of bandwidth. The BER rate for a given set of M-ary FSK using orthogonal frequencies is difficult to derive for the general case and must be normally calculated numerically (Proakis 2001).

PRINCIPLES OF PHASE MODULATION

Phase modulation (PM) is another form of angle modulation. Although it is not much used for analog signals, it is the modulation of choice for satellites, deep-space missions, and those occasions that require a strong noise immunity. When a phase is modulated with a particular modulating signal, the derivative of the phase (frequency) is also modulated with the same signal.

Phase modulation is expressed mathematically by varying the phase of a higher-frequency carrier with a constant frequency in Equation 4 [$s(t) = A \cos(\omega t + \Phi)$]. In the case of PM, the phase Φ is proportional to the modulating signal, $v_m(t)$:

$$\Phi(t) = k_p v_m(t) \quad (37)$$

in which the constant k_p is expressed in rad/V and is called *phase modulator sensitivity*.

Therefore, the general expression for the PM signal is:

$$s_{PM}(t) = A \cos(2\pi f_c t + k_p v_m(t)) \quad (38)$$

If we assume again a sinusoidal modulation signal $v_m(t) = V_{pk} \cos(2\pi f_m t)$, then the PM signal can be written as:

$$s_{PM}(t) = A \cos(2\pi f_c t + k_p V_{pk} \cos 2\pi f_m t) \quad (39)$$

Using $\Delta\Phi(t) = k_p V_{pk}$, Equation 39 becomes:

$$s_{PM}(t) = A \cos(2\pi f_c t + \Delta\Phi(pk) \cos 2\pi f_m t) \quad (40)$$

The value $\Delta\Phi(pk)$ represents the peak deviation of the sinusoidally varying carrier phase angle, so it can be seen as the modulation index for the PM signal. Therefore, Equation 40 can be rewritten as:

$$s_{PM}(t) = A \cos(2\pi f_c t + m_p \cos 2\pi f_m t) \quad (41)$$

It is interesting to compare this last equation with Equation 11, which describes the FM signal. We can see that both of them are similar with the difference being in the modulation term; for the FM signal, it is the derivative of the modulating signal. Figure 5 shows a block diagram for *narrowband phase modulation* (NBPM) generation in the more general case for the modulating signal.

Similar to the approach used to develop the narrowband FM signal and using the appropriate trigonometric identities and assuming a low modulation index ($\Delta\Phi < 0.25$), the equation for the NBPM signal can be written as:

$$s_{NBPM}(t) \approx A(\cos \omega_c t) - A(m_p \cos \omega_m t) \sin \omega_c t \quad (42)$$

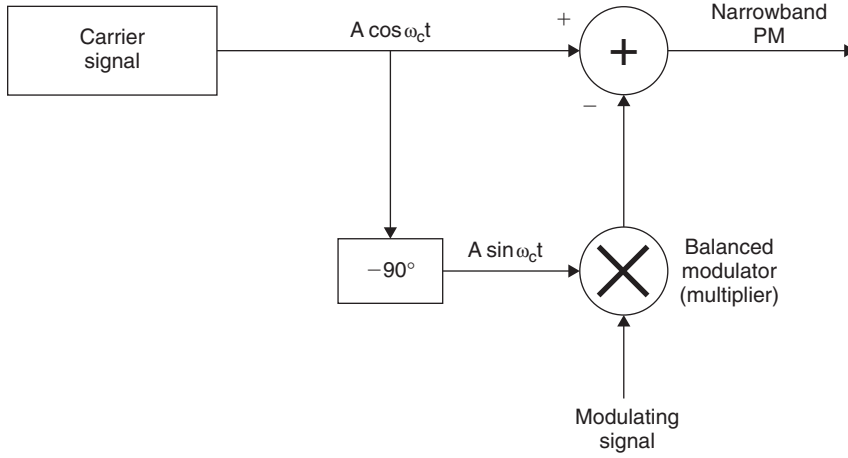

Figure 5: Block diagram for NBPM generation

Once again, it is possible to see the similarities between the equations that describe NBFM and NBPM signals with the difference in the sidebands being the different derivative.

Techniques for Phase Modulation Generation

When using a VCO, wideband phase modulators are the same as frequency modulators except that they first differentiate the modulating signal before entering the VCO. This and similar techniques can be used with the approaches regarding commercial integrated circuits that have been presented earlier for FM generation. For a given modulation index, the sidebands, spectrum, and power of the sinusoidal FM and PM are identical. The only way to see the difference between these two types of modulation in practice is by using a spectrum analyzer modifying the modulation frequency. The modulation index for the PM signal will remain constant, while for the FM signal it will change as the value m_f is dependent on f_m , but m_p and f_m are independent.

A difference in their practical use is that although a large number of practical systems use FM with analog and digital modulating signals, phase modulation is used almost exclusively with digital signals.

PHASE MODULATION FOR DIGITAL SIGNALS: PHASE SHIFT KEYING

A digital signal can also modulate a carrier by changing its phase. The resulting signal is called *phase shift keying* (PSK). The following sections will explore binary and multilevel phase shift keying systems.

Binary Phase Shift Keying

In PSK, the information is contained in the instantaneous phase of the modulated carrier. Usually, this phase is imposed and measured with respect to a known and selected phase of the carrier. For binary phase shift keying in which the modulating signal has two levels, the phase states are 0 and 180 degrees.

The basic method to generate BPSK is depicted in Figure 6. In this approach, the modulating signal has a

Figure 6: Basic approach for BPSK generation

bipolar form—that is, $v_m(t)$ can take these two values: $+A$ or $-A$ volts. The output of the BPSK generator can be written as:

$$v_{BPSK}(t) = v_m(t) A_c \sin \omega_c t \quad (43)$$

Using trigonometric identities, Equation 43 can be rewritten as:

$$v_{BPSK}(t) = A_c \sin(\omega_c t + \theta) \quad (44)$$

where the values of θ can be 0 or 180 degrees.

For coherent detection, the ideal PSK detector needs to know perfectly the phase of the unmodulated carrier. This requirement can be problematic because any phase error (Φ) of the locally generated carrier reduces the effective voltage at the output of the detector in $\cos(\Phi)$, thus degrading the signal-to-noise ratio. To avoid this problem, one particular process for detecting BPSK actually derives a phase-coherent reference, as shown in Figure 7.

Let us assume the signal at the input of the demodulator as:

$$v_{BPSK}(t) = B v_m(t) \sin \omega_c t \quad (45)$$

with B being the combined amplitude of the BPSK signal. The signal at the output of the squaring circuit is:

$$v_1(t) = B^2 v_m^2(t) \sin^2 \omega_c t = \frac{B^2}{2} v_m^2(t) (1 - \cos 2\omega_c t) \quad (46)$$

Figure 7: Detection of BPSK by extracting a phase-coherent reference from the signal

The original $v_m(t)$ had two possible values (A and $-A$). After the squaring circuit, $v_1(t)$ becomes:

$$v_1(t) = \frac{C^2}{2}(1 - \cos 2\omega_c t) \quad (47)$$

with the value $C=AB$ incorporating all of the amplitude values.

The bandpass filter eliminates the DC component, therefore, $v_2(t)$ is:

$$v_2(t) = \frac{C_1^2}{2} \cos 2\omega_c t \quad (48)$$

The signal $v_2(t)$ is then fed into a frequency divider. This divides the frequency by two and shifts the phase. The signal at its output, $v_3(t)$, is:

$$v_3(t) = \frac{C_2^2}{2} \sin \omega_c t \quad (49)$$

Finally, $v_3(t)$ is multiplied by the original BPSK signal given by Equation 44. The value of the resulting signal, $v_4(t)$ is:

$$\begin{aligned} v_4(t) &= \frac{C_1^2}{2} B v_m(t) (\sin \omega_c t) (\sin \omega_c t) \\ &= D v_m(t) \sin^2 \omega_c t = D v_m(t) (1 - \cos 2\omega_c t) \end{aligned} \quad (50)$$

The low-pass filter eliminates the last term in Equation 40, so the final output voltage is:

$$v_{out}(t) = D v_m(t) \quad (51)$$

The signal represented by Equation 51 is a reproduction of the original digital modulating signal that has been recovered from the BPSK signal. In practice, there are problems with this method, requiring the use of more sophisticated approaches such as differential data encoding and differential PSK modulation.

The BER for BPSK is given by Equation 52 (Bateman 1999):

$$BER_{PSK} = 0.5 \operatorname{erfc} \left(\sqrt{\frac{E_b}{N_o}} \right) \quad (52)$$

where $\operatorname{erfc}(x)$ is the complementary error function of the variable x , E_b is the detected energy per bit, and N_o is the noise spectral density.

M-ary Phase Shift Keying

We can apply the same concepts described for M-ary FSK to PSK signals, resulting in a M-ary PSK signal. The four-level PSK signal (quaternary encoding) remains in use, receiving the name of *quadrature phase shift keying* (QPSK). The QPSK signal has four different states that are determined by four different phase shifts for the transmitted signal. Therefore, the difference between phases is 90 degrees. Figure 8 shows a basic block diagram for the generation of the QPSK signal.

The digital modulating signal $v_m(t)$ is applied into a two-bit serial-to-parallel converter, so the resulting signals $v_1(t)$ and $v_2(t)$ change at one-half the rate of $v_m(t)$. This has the advantage of reducing the required transmission bandwidth as in the case of M-ary modulations. The output QPSK signal will be:

$$v_{QPSK} = v_1(t) \cos \omega_c t - v_2(t) \sin \omega_c t \quad (53)$$

Although the two terms that make up the voltage in Equation 45 are centered at the same carrier frequency and their magnitude spectra overlap each other, they do not interfere because they are in phase quadrature. In other words, all of the spectral components of the first term are 90 degrees out of phase with those of the second term, making them independent from each other.

The detection of the QPSK signal follows the inverse process as shown in Figure 9.

The QPSK signal is applied at the input of the demodulator and has the same form as Equation 45, although

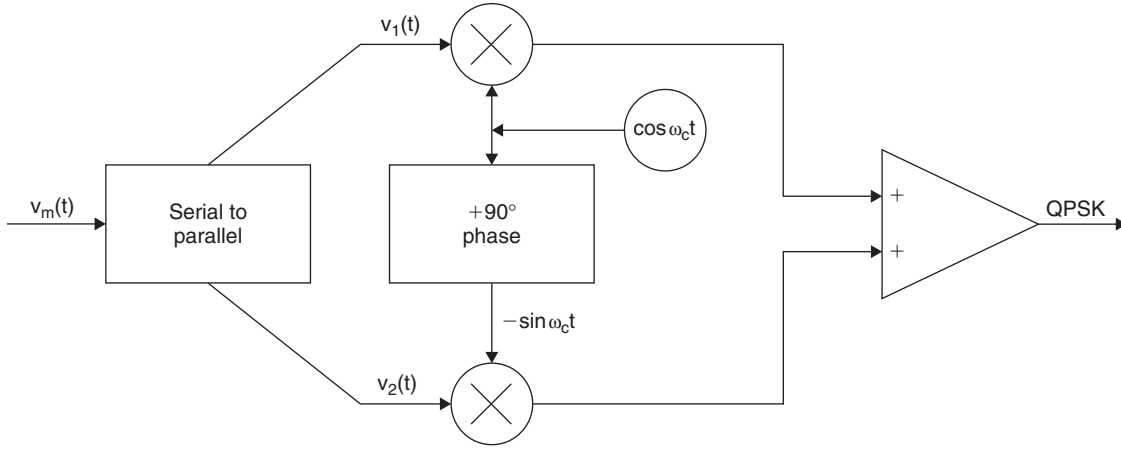

Figure 8: QPSK generation

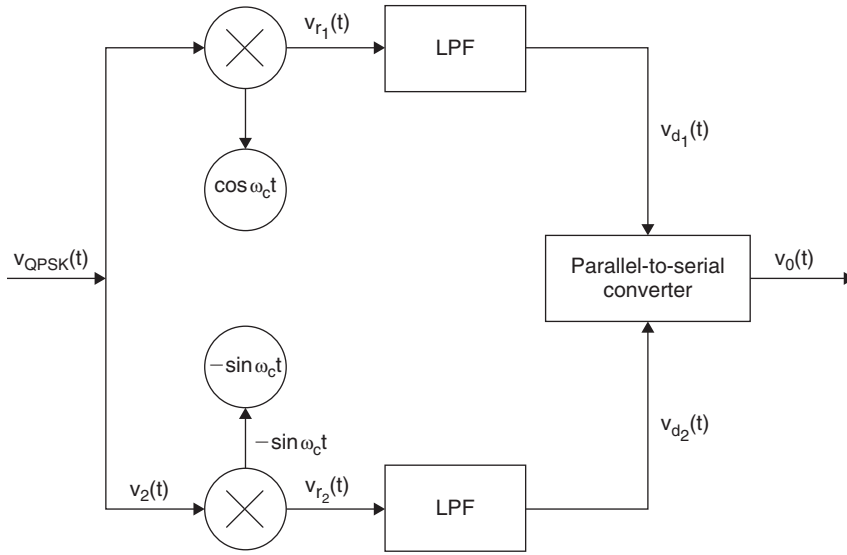

Figure 9: QPSK detection

with a different amplitude to indicate the changes in level during the transmission process:

$$\nu_{d,QPSK} = A \nu_1(t) \cos \omega_c t - A \nu_2(t) \sin \omega_c t \quad (54)$$

The expression for the signals at the output of the two multipliers, $\nu_{r1}(t)$ and $\nu_{r2}(t)$ after using the appropriate trigonometric identities are:

$$\begin{aligned} \nu_{r1}(t) &= \frac{A}{2} \nu_1(t) + \frac{A}{2} \nu_1(t) \cos 2\omega_c t - \frac{A}{2} \nu_2(t) \sin 2\omega_c t \\ \nu_{r2}(t) &= \frac{A}{2} \nu_2(t) - \frac{A}{2} \nu_2(t) \cos 2\omega_c t - \frac{A}{2} \nu_1(t) \sin 2\omega_c t \end{aligned} \quad (55)$$

The terms at $2\omega_c$ are eliminated by the low-pass filter, thus resulting in the following signals $\nu_{d1}(t)$ and $\nu_{d2}(t)$ at their output:

$$\begin{aligned} \nu_{d1}(t) &= \frac{A}{2} \nu_1(t) \\ \nu_{d2}(t) &= \frac{A}{2} \nu_2(t) \end{aligned} \quad (56)$$

Equation 56 shows the existence of two separate streams of digital data that are then combined into a single stream by the parallel-to-serial converter, thus recovering the original digital modulating signal.

QPSK modulation allows for sending information at twice the speed of BPSK using the same bandwidth without compromising the BER performance over BPSK at the expense of using multilevel signals. A recent variation of QPSK now widely used in the majority of digital radio modems is the format called $\pi/4$ QPSK. The difference between these two formats is that in $\pi/4$ QPSK the set of four symbols is rotated by 45 degrees at every new symbol transmission. This ensures that the modulation envelope of the filtered QPSK signal never crosses zero, so the peak to mean ratio of the modulation is minimized. This type of modulation can be easily implemented by a digital signal processor (Texas Instruments 1996).

More complex modulation schemes combine digital amplitude modulation with digital phase modulation, resulting in the *quadrature amplitude modulation* (QAM) approach. The analysis of these modulations goes beyond the scope of this article and can be easily found elsewhere in this volume.

The MAX2720 and MAX2721 integrated circuits from Maxim are direct QPSK modulators that are suitable for work in the 1.7 GHz to 2.5 GHz band and also incorporate a power amplifier to minimize the need for external parts in a design. Similarly, members of the MAX2361 family are complete quadrature QPSK transceivers optimized to work in cellular phones. Similar products can also be found from Texas Instruments—for example, the GC41164/6 quad digital transmitter chips. The AD7011 chip from Analog Devices is a $\pi/4$ DQPSK transmit port that employs a differential QPSK modulator with the $\pi/4$ rotation explained above, and the AD9853 from the same manufacturer is a programmable digital QPSK modulator that can also be employed for QAM transmissions (Maxim Semiconductor 2000).

CONCLUSION

Phase and frequency modulation are two types of angle modulation, which is based on changing the angle of a carrier signal in accordance with the amplitude of the modulation signal that contains the information to be transmitted. When the modulating signal is a digital signal, the resulting frequency-modulated signal and process receive the name of *frequency shift keying*, while for phase modulation it is named *phase shift keying*. This chapter has studied both analog and digital modulations, providing examples of commercial devices suitable for their hardware implementations. Although analog angle modulations have been prevalent in the past, digital angle modulations are now more widely used, leaving analog modulation mostly to broadcasting applications.

GLOSSARY

- Analog:** Pertaining to or consisting of a signal or parameter that is continuously and infinitely variable.
- Bandwidth:** The data-transmission capacity of a communications system, channel, network, or medium.
- Binary:** Based on or consisting of two parts, components, or possibilities.
- Demodulation:** The process of reversing the effects of modulation, thereby restoring the original modulating signal.
- Digital:** Pertaining to information, such as data, that is represented in the form of discrete units called *digits*, especially that expressed in binary digits.
- Frequency:** For a periodic phenomenon, the number of complete cycles per unit of time. When the unit of time is one second, the unit of frequency is the hertz.
- Modulation:** The process of modifying a characteristic of a wave or signal proportionally to a characteristic present in another wave or signal.
- Noise:** Usually, an unwanted electrical disturbance, often random or persistent in nature, that affects the quality or usefulness of a signal or adversely affects the operation of a device.
- Phase:** For a given periodic phenomenon, the portion of the complete cycle that has been completed as measured from a given reference point.

Spectrum: A range of energies arranged in order of increasing or decreasing wavelengths or frequencies.

INTRODUCTION

Carrierless amplitude phase (CAP) modulation is a standard used in computer networks in order to communicate at high data rates, often over relatively low-quality cable. A widely used application is in the provision of *asymmetrical digital subscriber lines (ADSL)*; these lines provide broadband network access to residential customers using the same unshielded copper twisted pairs already used for voice telephony and ISDN services (Paradyne Corporation 2000). In many such cases, this use has been superseded by more elaborate *discrete multitone (DMT)* systems that are favored for their ability to counter narrowband interference. CAP, however, is still widely used in many countries. It has also found applications in *asynchronous transfer mode (ATM) local area networks (LANs)* using low-quality unshielded cabling for high data-rate communication (Im et al. 1995). In both of these applications, CAP modulation has been adopted primarily because of its high bandwidth efficiency and low implementation costs.

FUNDAMENTALS OF AMPLITUDE PHASE MODULATION

Many of the underlying principles behind CAP are identical to those of *quadrature amplitude modulation (QAM)*. The only fundamental difference between them is in their implementation. Figure 1 illustrates block diagrams of a QAM transmitter and receiver as well as those of an equivalent CAP transmitter and receiver.

In either case, the first part of the transmission process is *encoding*. This stage splits the incoming data stream into blocks of binary data, usually between two and eight bits, depending on the modulation scheme. Each block of data is encoded into a single pair of amplitude-weighted impulses. The amplitude weights, denoted a_n and b_n (n being the symbol index), are chosen from a look-up table and are often referred to as a single complex value, $A_n = a_n + jb_n$. A plot of all possible values of A_n on the complex plane is known as the *signal constellation*. Figure 2 shows

an example of how four bits can be encoded in this way. CAP line codes are usually referred to in the form CAP- M (or sometimes M -CAP), where M is the number of points in the signal constellation. The example in Figure 2 is for a sixteen-point constellation, hence CAP-16. Sixteen permutations of a_n and b_n allow the transmitter to encode four bits per symbol. In general, $\log_2(M)$ bits per symbol are encoded.

After encoding, the subsequent modulation is then performed in such a way that two orthogonal signals are produced. These are then summed together before transmission. Upon reception, the orthogonality of the two summed modulated signals allows them to be separated, after which the a_n and b_n values can be estimated and the original encoded data symbol recovered. The last stage is to decode the symbol, A_n , in order to recover the block of binary digits that was transmitted.

The difference between a QAM and CAP system is how the two streams of amplitude-modulated impulses generated by the encoder are transformed into a pair of band-limited, orthogonal, modulated signals in the transmitter and how the amplitudes of the original impulses are recovered in the receiver.

In the QAM transmitter, modulation is a two-stage process. The encoder output symbols are first low-pass filtered. This restricts the bandwidth of the signal to that of the transmission channel and, consequently, spreads the data impulses in the time domain (see Figure 3). The envelope of an individual symbol is the same as the impulse response of the filters. Therefore, they are often referred to as *pulse-shaping filters*. The baseband signal produced by the pulse-shaping filters is then multiplied by either the in-phase or quadrature phase carrier (i.e. a sine or a cosine wave). This produces a pair of orthogonal modulated signals, which are simply summed before transmission.

Carrierless Amplitude Phase Modulation

In a CAP modulator, the low-pass filtering and modulation are effectively combined into a single pair of filters,

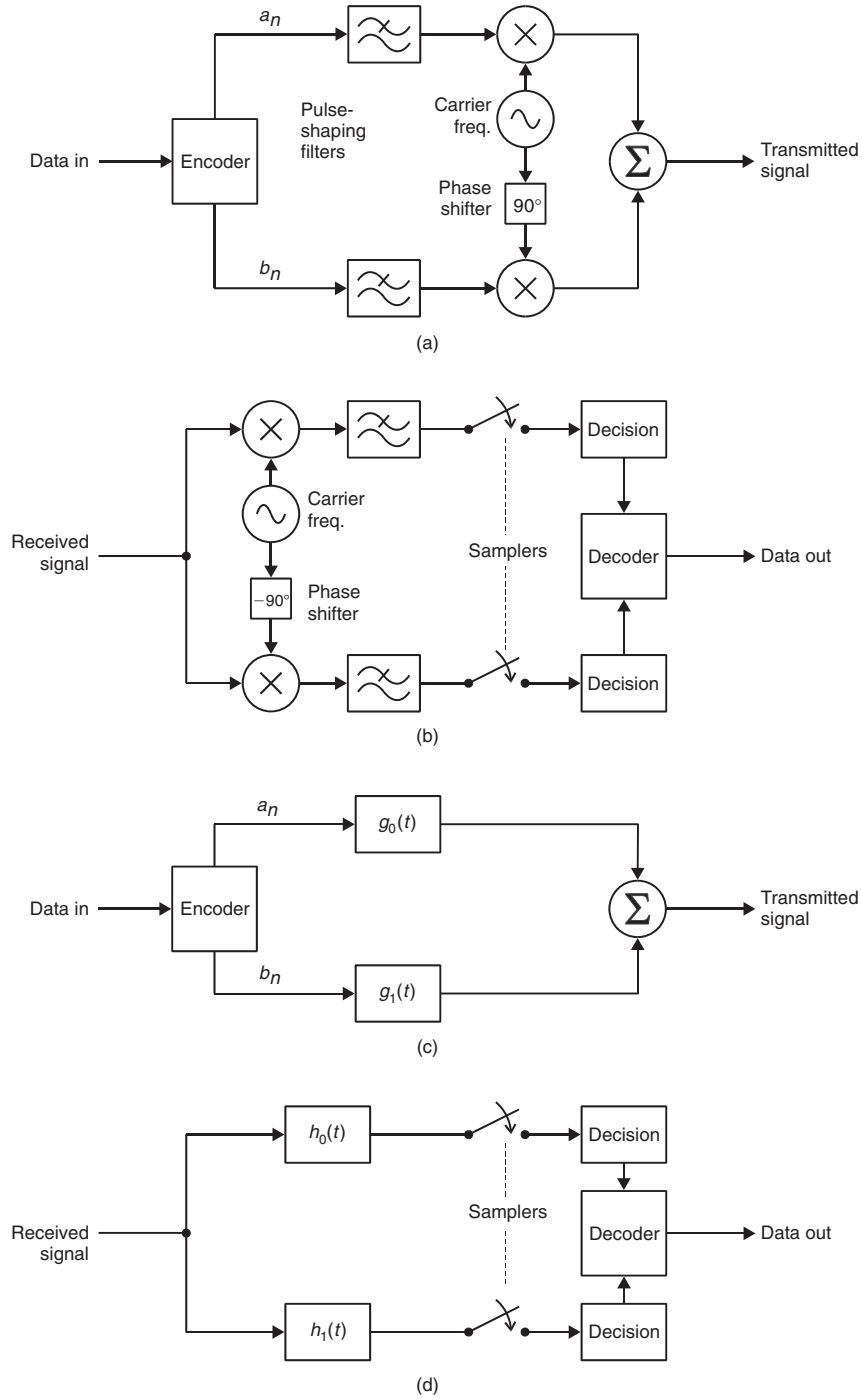

Figure 1: (a) QAM transmitter, (b) QAM receiver, (c) CAP transmitter, (d) CAP receiver

one for each channel. The filters are designed to be orthogonal and to have a bandpass response according to the requirements of the transmission channel. Usually, this is achieved by designing the two impulse responses to have the same amplitude envelope multiplied by either a cosine or a sine wave. Figure 4 shows the impulse responses of a pair of filters suitable for this purpose.

The bandpass responses of the filters means that the signals produced will already be centered at the required carrier frequency and will also be orthogonal. As no separate

carrier frequency multiplication is required, this scheme is known as *carrierless amplitude phase modulation*.

It is clear that the design of the pair of filters determines the bandwidth that the modulated signal will occupy. This, in turn, is specified by the intended application. For example, a typical upstream ADSL channel may occupy the band of frequencies between 30 kHz and 160 kHz. In this case, the filters must be designed to have a center frequency of 95 kHz and a bandwidth of 130 kHz. This implies a maximum symbol rate of 130 kbaud,

Figure 2: Signal constellation for a CAP-16 or QAM-16 encoder

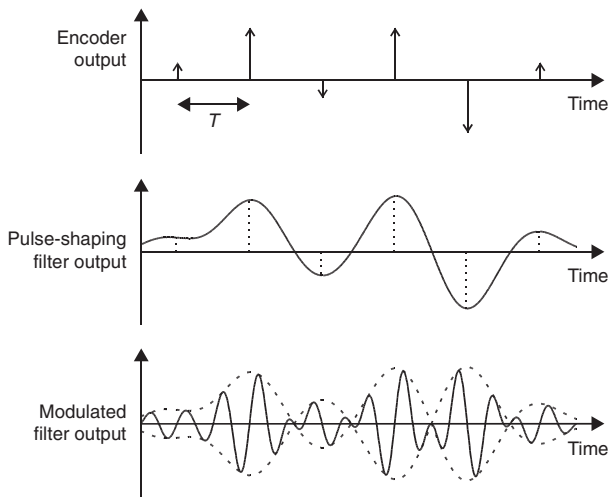

Figure 3: Example waveforms from one channel of a QAM modulator

Figure 4: Impulse responses of a pair of orthogonal filters

although in practice an excess bandwidth of up to 100 percent is employed, giving typical symbol rates of between 65kbaud and 100kbaud. If CAP-16 is used, then each symbol would represent four bits, giving a data rate of between 260kbits and 400kbits per second.

In the 51.84Mbps ATM LAN application described by Im et al. (1995), on the other hand, the band used is between 0 and 25.92 MHz, giving a center frequency of 12.96 MHz and a bandwidth of 25.92 MHz. In this system, the excess bandwidth is 100 percent, so the symbol rate is exactly half the bandwidth at 12.96 Mbaud. This particular system uses CAP-16 giving four bits per symbol and, therefore, the final data rate of 51.84 Mbps.

Carrierless Amplitude Phase Modulation versus Quadrature Amplitude Modulation

A reasonable question at this stage would be “Which is better—CAP or QAM?” The answer would be, “It depends on the implementation.” A glance at Figure 1 would suggest that the CAP implementation is much simpler. It does, however, require precisely designed filters to ensure orthogonality. In practice, this is trivial in a software implementation using a pair of *finite impulse response* (FIR) filters but much more difficult in a hardware-only system. By contrast, the QAM architecture consists only of elements that are relatively straightforward to implement in hardware.

In terms of the fundamental limitations in performance, a CAP system can be considered identical to an equivalent QAM one. There are, however, practical differences that arise because of the differences in the receiver implementation. In particular, the effects of carrier frequency tracking and symbol timing synchronization are different in their nature.

IMPLEMENTATION

Transmitter Implementation

Referring to the block diagram in Figure 1, the transmitted signal can be written as:

$$s(t) = \sum_{n=-\infty}^{\infty} [a_n g_0(t - nT) + b_n g_1(t - nT)] \quad (1)$$

where a_n and b_n are the real and imaginary parts of A_n , the n th encoded data symbol; T is the symbol period; and $g_0(t)$ and $g_1(t)$ are the impulse responses of the in-phase and quadrature phase filters, respectively. The design of these filters must fit the following specification:

- The bandwidths of the filters do not exceed the bandwidth of the transmission channel, and
- the impulse responses of the two filters are orthogonal with respect to one another—that is, $\int g_0(t)g_1(t)dt = 0$.

The reason for the first criterion is obvious; one job of the pulse-shaping filters is to restrict the bandwidth of the signal. The second criterion is required to ensure that the two components of each data symbol— a_n and b_n —can be separated in the receiver. In practice, satisfying these

criteria is achieved by using filters that form a Hilbert pair (i.e., the Fourier transform of one is identical to that of the other, only rotated through a phase shift of 90 degrees). Usually, the form of the two filters will be

$$g_0(t) = w(t)\cos(2\pi f_c t) \text{ and } g_1(t) = w(t)\sin(2\pi f_c t) \quad (2)$$

where $w(t)$ is the amplitude window function common to both filters and f_c is the center frequency of the transmission channel. Provided that the center frequency is higher than the largest frequency component of the amplitude window, the cosine and sine functions ensure that the orthogonality condition is satisfied. They also allow the signal to be modulated to a specified center frequency, f_c . The window function, $w(t)$, is designed to shape the spectrum of the transmitted signal and restrict it to the specified bandwidth.

A commonly used family of amplitude windows is the *raised cosine form*, so named after the shape of their Fourier transform (Chen, Im, and Werner 1992). Such windows are favored because the spectrum is well confined to a predictable bandwidth without the requirement for filters with excessively long impulse responses. Figure 5 shows an example of a raised cosine window (a *von Hann*

window) in the time and frequency domains. It can be seen that the spectral energy is well contained within the bandwidth, $2/T$ (i.e., 100 percent excess bandwidth in this case). In the time domain, $w(t)$ theoretically extends infinitely. In practice, however, the temporal side lobe levels decay quickly, and the response can be truncated without adversely affecting the frequency spectrum.

Square-root raised cosine filters are another popular choice. These have the advantage that the energy is spread a little more evenly in the frequency domain although higher side lobes in the time domain necessitate longer filter responses.

Receiver Implementation

When a CAP signal is received, it is processed by separate in-phase and quadrature phase filters with impulse responses of $h_0(t)$ and $h_1(t)$. To optimize the performance of the system against additive white Gaussian noise, one would expect these to be matched filters—that is, their impulse responses would be time-reversed versions of $g_0(t)$ and $g_1(t)$. In many cases, however, this is not used because it would result in an undesirable amount of *inter-symbol interference* (ISI). As an example, Figure 6 shows the effect of using a matched filter for a raised cosine

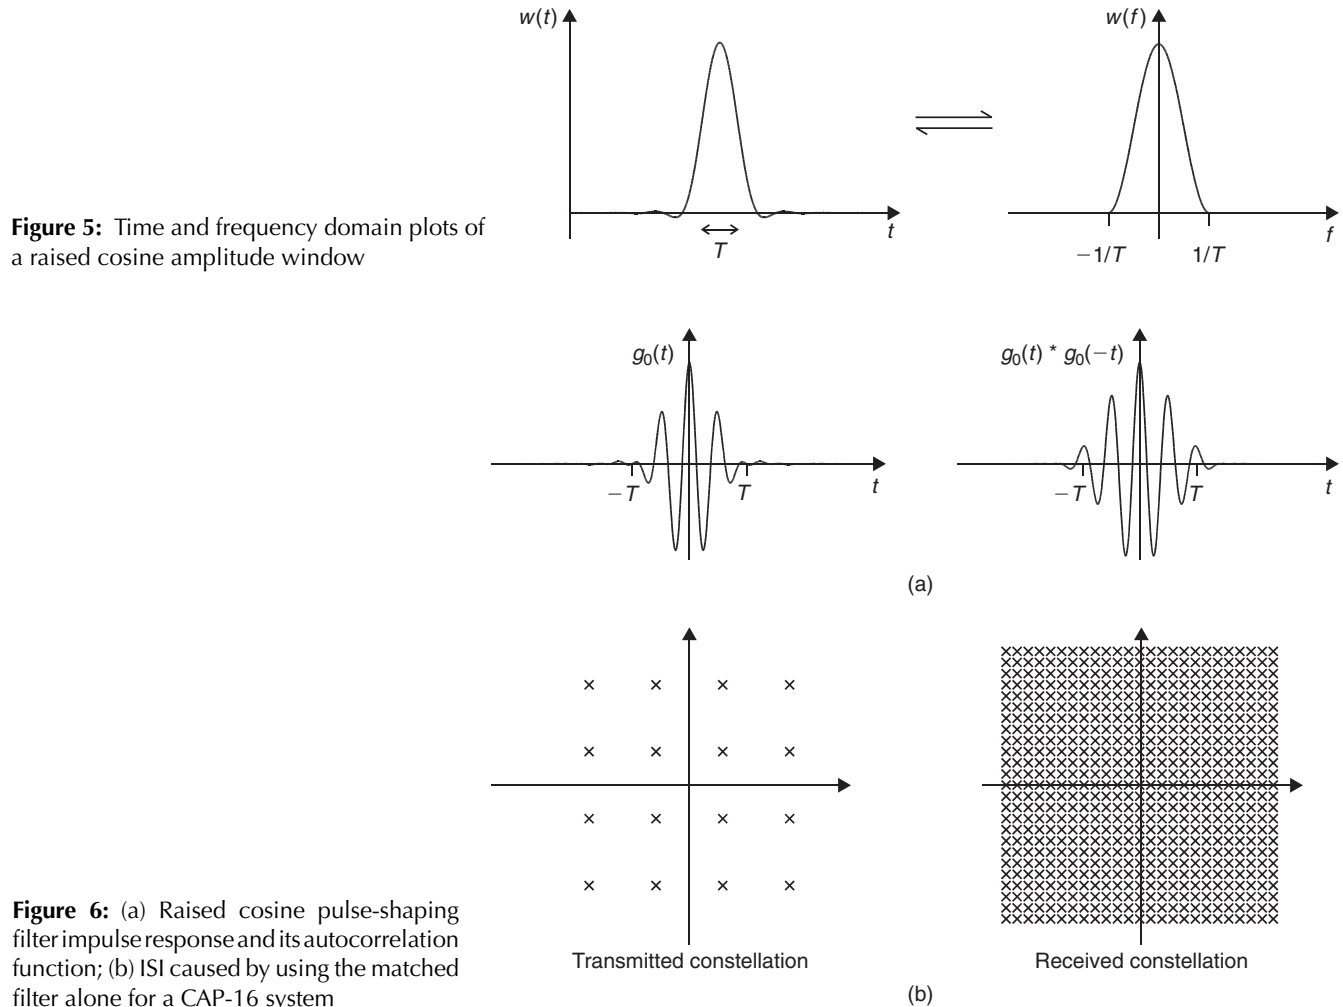

Figure 5: Time and frequency domain plots of a raised cosine amplitude window

Figure 6: (a) Raised cosine pulse-shaping filter impulse response and its autocorrelation function; (b) ISI caused by using the matched filter alone for a CAP-16 system

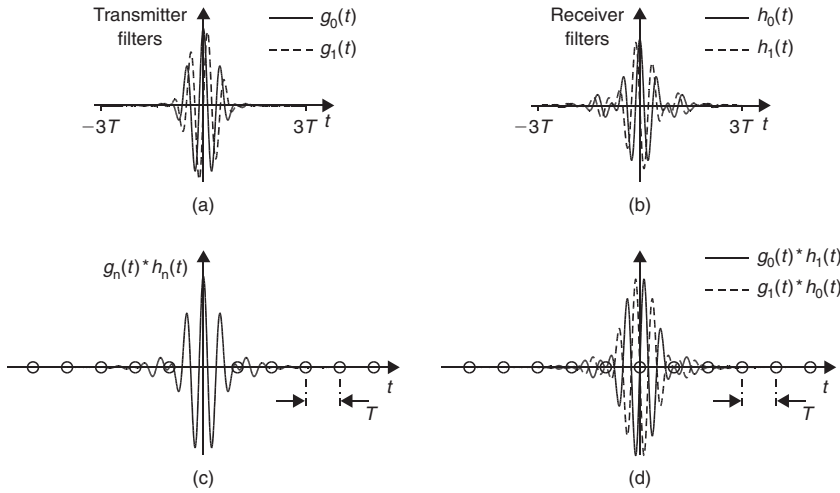

Figure 7: (a) Pair of raised cosine transmitter filter impulse responses, (b) their corresponding receiver filter responses, and (c and d) the convolution of the two. Circles indicate values that should be zero to ensure perfect reconstruction.

pulse-shaping filter with 100 percent excess bandwidth. Note that at delays of $\pm T$, the autocorrelation function of the filter response is a significant nonzero value. This translates into the ISI apparent in Figure 6a.

Ideally, the filters used in the receiver should be designed such that the following conditions are satisfied:

- $g_n(t) * h_n(t)$ is unity for zero time delay,
- $g_n(t) * h_n(t)$ is zero for time delays that are nonzero integer multiples of T , and
- $g_n(t) * h_{1-n}(t)$ is zero for all time delays that are integer multiples of T , including zero,

where $n = 0$ or 1 and $*$ represents convolution.

An example of an appropriate pair of transmitter and receiver filter responses is shown in Figure 7.

Adaptive Filtering

Although it is possible to design appropriate receiver filter responses in advance that meet the criteria above, this is seldom done in practice mainly because the ISI caused by the transmitter filter is often insignificant when compared with the ISI caused by the response of the channel itself.

The channel response obviously will vary from application to application. In most cases, however, propagation through a communications channel can be modeled as

$$y(t) = \sum_m c_m s(t - \tau_m) + n(t) \quad (3)$$

where $y(t)$ is the received signal, $s(t)$ is the transmitted signal, $n(t)$ is the additive noise or interference, and the coefficients c_m and τ_m correspond to the attenuation and the propagation loss of the m th discrete propagation path from source to receiver. The physical mechanism that causes multiple propagation paths depends on the application. For example, in a wireless system it will be the result of multiple reflections from scatterers near the propagation path. In a cabled system, however, it will result from reflections along the cable caused by scattering at impedance-mismatched junctions.

An alternative and more compact form of Equation 3 is:

$$y(t) = c(t) * s(t) + n(t) \quad (4)$$

where $c(t)$ is the impulse response of the channel. Note that $c(t)$ can rarely be considered to be completely time-invariant. For example, when communicating via a cable the channel response will appear to be relatively constant but will, in fact, change slowly over time as environmental conditions evolve. In a mobile wireless communications scenario, by comparison, $c(t)$ will be continually varying over time as the relative positions of the transmitter, receiver, and scatterers change.

A nonideal channel impulse response causes ISI in just the same way as the transmission filter and its effects therefore can be cancelled (or at least suppressed) in the same way by designing an appropriate receiver filter. There are, however, two significant differences. First, the ISI caused by the channel can often have a much greater extent, affecting several symbols rather than just the immediate neighbors. Also, the channel response is not necessarily known in advance and may, in fact, vary with time. For the latter reason, adaptive filters (also known as *adaptive equalizers*) are generally employed for the two receiver filters. Figure 8 shows an example of a simulated channel response and the measures that an adaptive filter takes in order to correct (or equalize) it.

In fact, there are various adaptive filter designs that can be used to suppress ISI (Qureshi 1985). The simplest form is a linear feed-forward equalizer (as used in Figure 8), usually a finite impulse response filter whose tap weights are determined adaptively in order to minimize the difference between the input and output of the decision-making block. In applications with high signal-to-noise ratios, the response of the adaptive filter will iteratively converge toward the convolution of the ideal receiver, $h_n(t)$, and the band-limited inverse filter to the channel response. There are, however, problems with this approach. First, to perfectly equalize the channel response with a linear equalizer, long adaptive filter responses may be needed. The ideal inverse filter response will often be several times longer than the spread of the channel. Not only are long filters more

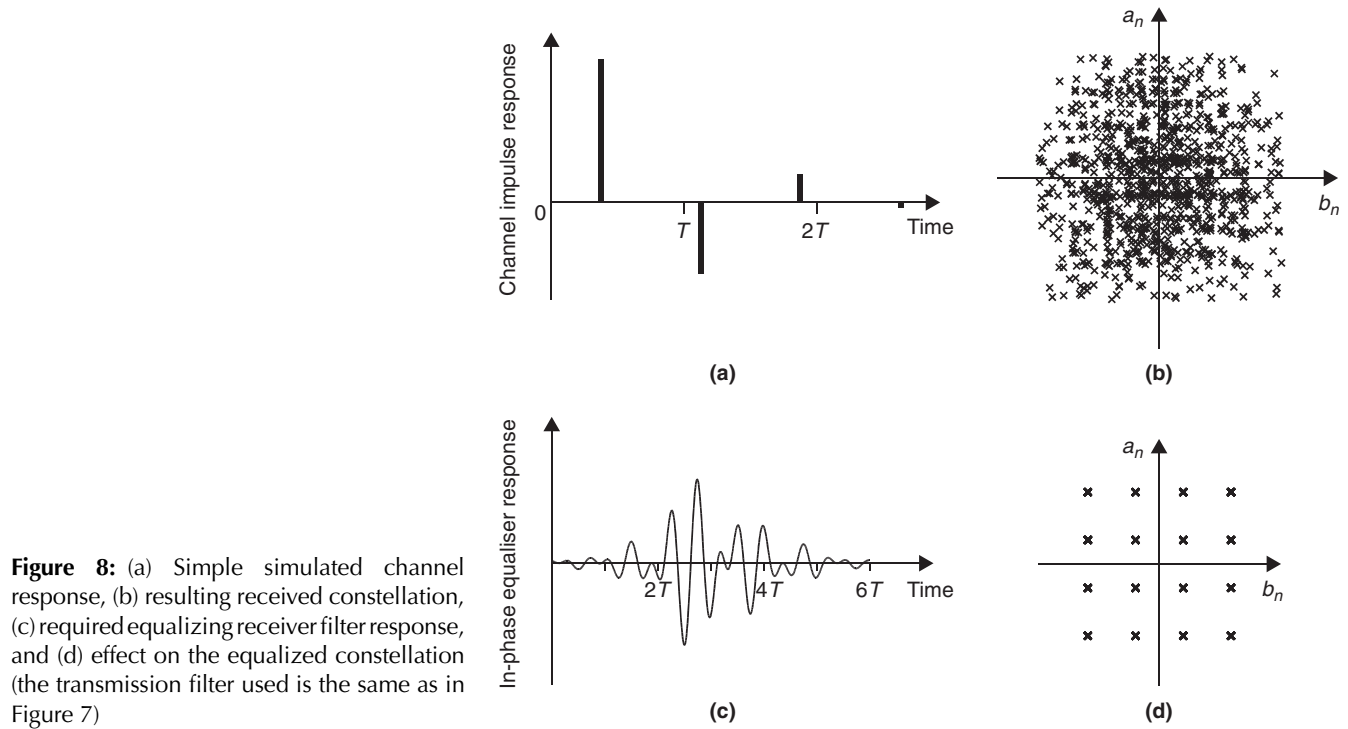

Figure 8: (a) Simple simulated channel response, (b) resulting received constellation, (c) required equalizing receiver filter response, and (d) effect on the equalized constellation (the transmission filter used is the same as in Figure 7)

computationally costly to implement but also they adapt more slowly. Second, if the channel response exhibits deep nulls in the frequency domain, then a linear equalizer will attempt to correct for this by introducing high gains at those frequencies. This can result in the ambient noise being amplified undesirably, giving no net improvement in the final error rate and perhaps even increasing it.

A more effective approach is often the use of a non-linear equalizer, typically employing a decision feedback equalizer (Proakis 1995). A block diagram of a CAP receiver with decision feedback equalization is shown in Figure 9 (Zlatanovici et al. 1999).

The equalizer consists of two types of filters: feed-forward and feedback. Effectively, the feedback filters take the decisions made for previous symbols, convolve them with an estimate of the channel response, and then subtract this from the input to the decision block. Both the in-phase and quadrature phase decisions must be fed back for each equalizer, resulting in four adaptive feedback filters in total. If the combined channel response and transmitter filter is minimum phase (i.e., there are no precursors to the main arrival), then the feedback filters alone can perfectly cancel out the ISI. This assumes that the filter length is at least as long as the spread of the channel

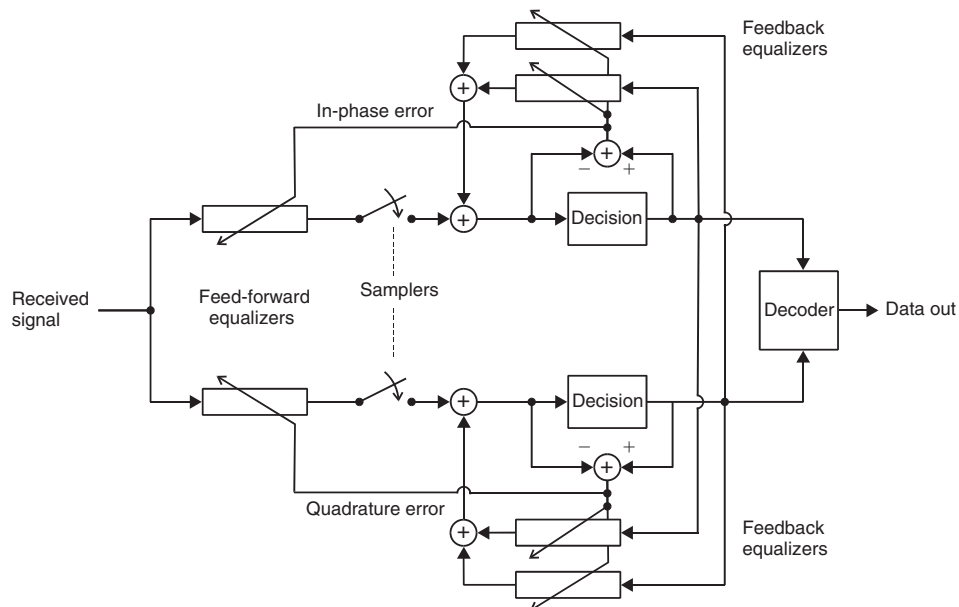

Figure 9: CAP receiver with nonlinear decision-feedback equalization

Figure 10: NEXT and FEXT interference sources

and that all the decisions are correct. Typically, the transmitter filter response is not minimum phase, so the feed-forward filters are also needed to gather together the energy spread within one or two symbols from the current sample point. By incorporating feedback filters, the feed-forward filters can usually be quite short, often no more than a few taps in length.

The tap weights of the filters are derived adaptively in an attempt to constantly minimize the error signal. Several adaptive algorithms exist for this purpose. The choice of algorithm typically is a compromise among rate of adaptation, steady-state error, and computational complexity. For applications with cable as the transmission medium, the propagation path is relatively stable. In such cases, a simple *least mean squares* (LMS) algorithm is sufficient. For more variable channels such as wireless, optical, or acoustic ones, however, a more rapidly adapting algorithm such as the *recursive least square* (RLS) can be more appropriate.

Cross Talk

Like any form of cabled transmission, CAP systems are vulnerable to interference sources sharing the same bandwidth. Cross talk is a particular type of interference caused by signals being coupled from other pairs of wire sharing the same cable. It is distinct from other forms of interference in that it is possible to suppress it using techniques other than simply improving the shielding of the cables. Figure 10 shows the sources of cross talk in a cable sharing several pairs of wires.

Two types of cross talk are illustrated in Figure 10: *near-end cross talk* (NEXT) and *far-end cross talk* (FEXT). NEXT is caused by a transmitter interfering with the reception of neighboring equipment at the same end of the cable. Receiver A is subject to NEXT from the transmitter in Figure 10. FEXT, on the other hand, is caused when a transmitted signal interferes with reception at the opposite

end of the cable as with receiver B in Figure 10. In general, as a consequence of the propagation loss along the length of the cable, NEXT is a much stronger source of interference than FEXT and is often the only one that is processed against. NEXT suppression can be achieved most easily when the source of the cross talk is employing the same modulation scheme as the desired signal to be received. This situation is sometimes known as *self-NEXT*. The two most common approaches to suppress NEXT are *NEXT cancellation* and *NEXT equalization*.

NEXT cancellation works by introducing an extra adaptive filter into the system as illustrated in Figure 11. The new filter attempts to simulate the NEXT propagation path from the transmitter, causing the interference to the receiver suffering from it. Adaptive filtering, driven by the receiver error signal, is used in a similar way as in a decision feedback equalizer. When the adaptive filter response converges toward the same transfer function as the NEXT path, the interference will be completely subtracted from the incoming signal. Note that the diagram in Figure 11 assumes that there is only one source of NEXT. This implies that the cable contains just two pairs of wires and that there is only one transmitter and one receiver at each end of the cable. If there are more NEXT sources, then extra cancellation filters are required.

NEXT equalization works using exactly the same adaptive equalization architecture already discussed. The only difference is that the receiver filters now have an extra constraint to satisfy, as explained below. If the impulse response of the transmission channel is denoted by $p_{TX}(t)$ and the impulse response of the NEXT interference path is denoted by $p_{NEXT}(t)$, then the receiver filters must satisfy the following criteria:

1. $g_n(t) * p_{TX}(t) * h_n(t)$ is unity for zero time delay,
2. $g_n(t) * p_{TX}(t) * h_n(t)$ is zero for time delays that are non-zero integer multiples of T ,

Figure 11: Simple NEXT canceller

Figure 12: Convolution of the transmission filter and simulated channel impulse responses after NEXT equalization

3. $g_n(t) * p_{TX}(t) * h_{1-n}(t)$ is zero for all time delays that are integer multiples of T , and
4. $g_n(t) * p_{NEXT}(t) * h_n(t)$ and $g_n(t) * p_{NEXT}(t) * h_{1-n}(t)$ are zero for all time delays that are integer multiples of T where $n = 0$ or 1 in each case.

Note that the first three criteria are the requirements for successful operation with no cross talk. The fourth criterion is the extra constraint. Figure 12 shows an example of the convolved impulse responses of the in-phase transmitter and receiver filters and simulated transmission and NEXT propagation channels. Note that the equalized responses are zero for all integer multiples of the symbol period, T , except for the transmission channel response, which is unity at zero time delay.

The extra constraint that the presence of NEXT imposes on the adaptive equalizer cannot be satisfied without cost. To successfully equalize both a transmission channel and a NEXT source, an extra degree of freedom is required in the shape of considerable excess bandwidth and a fractionally spaced linear equalizer (Petersen and Falconer 1991). In theory, an additional 100 percent excess bandwidth is required for each NEXT source to be equalized. In practice, systems rarely use more than 100 percent excess bandwidth in order to maintain bandwidth efficiency, in which case the receiver will automatically equalize the most dominant NEXT source. This situation can compare favorably against the additional requirements of several NEXT cancellers under the same circumstances. It has been observed (Im et al. 1995) that NEXT cancellation receivers, in general, do not operate reliably in a multiple interferer scenario.

TIMING AND SYNCHRONIZATION

Synchronization Requirements

As with any coherent communications system there is an exacting requirement for the receiver and transmitter clocks to be locked in terms of both their frequency and phase. In QAM systems, two oscillators must be synchronized: the carrier frequency for downconversion and the symbol-timing clock for sampling the data symbols (Franks 1980). In a CAP receiver, by comparison, there is no carrier frequency and only the symbol-timing clock must be synchronized. This does not necessarily make the

Figure 13: Effect of uncompensated 0.01 percent timing drift on 200 symbols in a CAP-16 system

task any simpler because the tolerance requirements are much more stringent in a CAP system than the symbol-clock tolerance limits in an equivalent QAM receiver. Figure 13 shows the effects of a 0.01 percent error in the receiver clock frequency of a CAP system of more than 200 symbols. In an equivalent QAM receiver, such an error in the symbol timing would be imperceptible. The effect observed in Figure 13 is broadly equivalent to an error in the downconverter oscillator rather than the symbol timing. With CAP demodulation, a single clock effectively performs both tasks.

Note that the simulation used for Figure 13 did not incorporate any kind of timing compensation. In practice, the adaptive equalizer would constantly attempt to minimize the error and would partly compensate for the timing drift. This would lead to tap rotation whereby the coefficients of the feed-forward equalizers shift toward the left or the right in an attempt to counter the drifting clock. Eventually, the equalizers would fail as they would run out of taps, so it is essential that some form of external symbol-timing recovery processing is also used.

Synchronization Implementation

There are two main categories of algorithm and circuit used to recover the symbol timing from a coherently modulated received signal: *decision-directed* and *non-decision-directed*. These are also known as *data-aided* and *nondata-aided* systems in some texts. In a decision-directed system, the data outputs from the receiver are fed back and compared with the input to the decision block.

Figure 14: Simple symbol-timing recovery circuit

The phase difference between the two is measured and averaged over time by suitable filtering. Any nonzero average phase error can be interpreted as the receiver clock being slightly ahead or behind the transmitter clock and can be compensated appropriately. The detail of how this basic idea is achieved varies between systems but most are based on this fundamental idea.

A simpler method that has found favor in many CAP applications is a nondecision-directed approach. Nondecision-directed symbol-timing estimators generally try to extract the timing information completely independently from the rest of the receiver. They do this by attempting in some way to extract the cyclostationary statistics of the received signal and recover the cyclic frequency that will correspond to the symbol rate of the modulated data. A simple example of a nondecision-directed symbol timing recovery circuit is shown in Figure 14.

CAP signals exhibit *cyclostationarity* in that their variance is not constant over time but varies periodically with the symbol rate. The circuit in Figure 14 recovers this cyclic frequency by a relatively simple process. First, the signal is prefiltered, often by a matched filter, to optimize the noise performance of the estimator. Then a squarer is used to generate a stable tone at the symbol rate. After squaring, the signal will still contain unwanted artifacts caused by the data symbols. A postfilter in the form of a narrowband filter centered at the expected symbol rate extracts the exact symbol rate and suppresses the jitter caused by the variations of the data themselves.

Figure 15 shows the spectra of typical CAP signals as they are being processed by such an estimator. Note the spikes at frequencies of $\pm 1/T$ in the squarer output spectrum; this is the desired symbol timing frequency. Although it is clear to see these spikes on the spectrum, there is obviously also a large amount of “noise” at other frequencies that must be suppressed by the bandpass filtering provided by the postfilter. Finally, the phase-locked loop locks onto the symbol rate frequency and generates the sample clock to be used by the CAP demodulator.

There are numerous variations on this basic theme. In some cases, the squaring operation is replaced by a different nonlinear function (Proakis 1995); in others, the prefiltering is made slightly more elaborate in an attempt to reduce timing jitter. In particular, the use of two separate prefilters, both narrowband but centered at different frequencies $1/T$ apart, is a promising approach (Kim et al. 1998). Instead of a squarer, the outputs of the two filters are multiplied together before postfiltering. This has the advantage of reducing timing jitter and also reducing the oversampling requirements of the receiver signal processor.

Acquisition

The discussion of adaptive equalization, NEXT equalization, and synchronization all make the assumption that

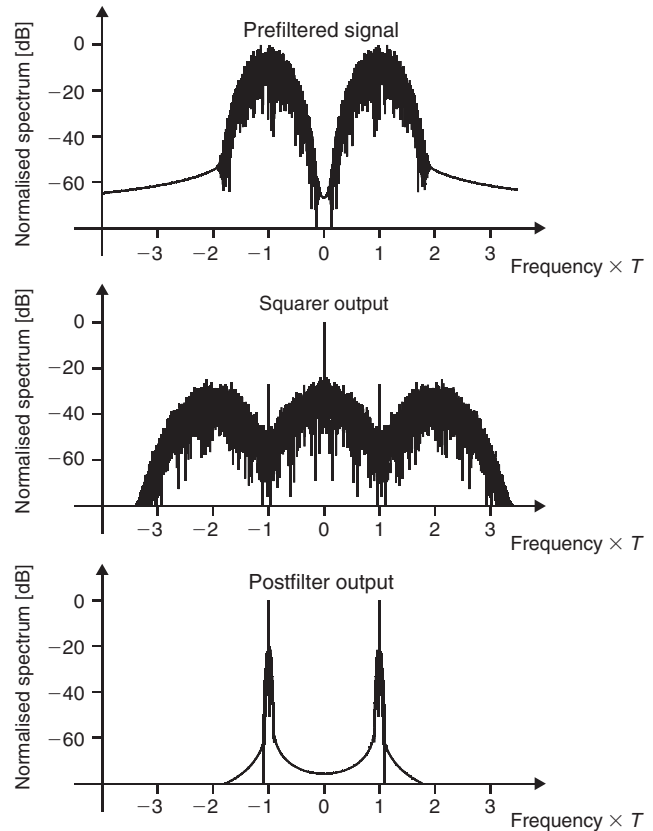

Figure 15: Prefiltered CAP signal, squarer output, and postfilter output

the receiver is already running and that the equalizer has already converged. In other words, the equalization and timing recovery sections of the receiver are operating in a tracking mode rather than an acquisition one. When the receiver is first switched on and connected, the adaptive filter coefficients will not equalize the channel because they have not had a chance to adapt to it. As a result, any initial amplitude and phase estimates made by the receiver will be erroneous because of the uncompensated ISI. This, in turn, will hinder the convergence of the equalizers and make the phase of the timing recovery circuit unreliable.

To allow the receiver to initialize successfully, preset training or synchronization sequences of data are usually inserted periodically into the transmission. On start-up, the receiver waits for a synchronization sequence that can be identified using correlation (or similar) processing. During the first and subsequent synchronization sequences, the equalizers can adapt based on the difference between the filter output and the known data symbols rather than the decoded estimates. This means that equalizer convergence is not hindered by the effects of noise

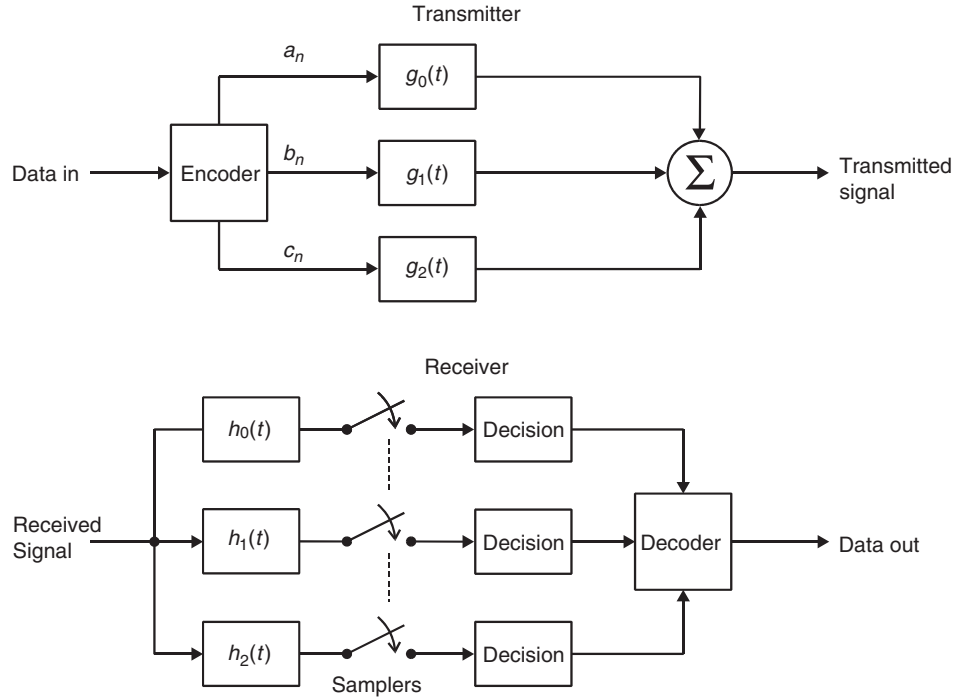

Figure 16: Three-dimensional CAP transmitter and receiver

caused by incorrect decisions. Furthermore, as the ISI and any NEXT interference are suppressed, the phase of the clock recovery circuit will become much more closely aligned with the correct transmitted phase. Depending on the nature of the channel response, adequate equalizer convergence can often be achieved after just a few tens of symbols so the overhead incurred by their occasional insertion into the transmission is not necessarily significant.

MULTIDIMENSIONAL CARRIERLESS AMPLITUDE PHASE MODULATION

Three-Dimensional Carrierless Amplitude Phase Modulation

For a CAP system to work, it is vital that the transmitter-receiver filter combinations satisfy the orthogonality (or “perfect reconstruction”) criteria outlined earlier. It has been proposed that it is possible to synthesize sets of more than two filter pairs that satisfy this condition while retaining appropriate spectral constraints. Given that this is possible, one has the potential to build a multidimensional CAP system (Shalash and Parhi 1999). Figure 16 shows a block diagram of such a system.

Having three transmission filters means that there are now three streams of encoded data that can be transmitted simultaneously instead of two. In Figure 2, the constellation of a two-dimensional CAP system with four possible signal levels per channel (a or b) was shown. Four levels per channel equates to $4^2 = 16$ possible symbols. Using four levels per channel again in a three-dimensional CAP system gives us $4^3 = 64$ possible symbols (i.e., an increase from four to six bits per symbol). The signal constellation for this system is shown in Figure 17.

Figure 17: Three-dimensional CAP-64 signal constellation

For this system to work, the perfect reconstruction criteria must be satisfied. These were outlined earlier for conventional two-dimensional CAP. In a system of arbitrary dimension, D , the criteria may be rewritten as

$$r_{nm}(kT) = \begin{cases} \delta(k) & \text{if } n = m \\ 0 & \text{if } n \neq m \end{cases} \quad (5)$$

where $r_{nm}(\tau) = g_n(t) * h_m(t)$, $n = 0, 1, \dots, (D - 1)$, $m = 0, 1, \dots, (D - 1)$, k is any integer, and $\delta(k)$ is the Kronecker delta function.

There are several ways to satisfy the conditions of Equation 5. One is to specify the desired transmission filter amplitude response and then search for a set of responses that satisfy Equation 5 while approximating the desired

spectral shape as closely as possible. The search is performed using a minimax optimization algorithm (Shalash and Parhi 1999).

Several flaws have been observed with this approach (Tang, Thng, and Li 2003). In particular, neglecting to constrain the spectral shape of the receiver filters can make this system highly noise-sensitive in a practical application. An alternative optimization method has been proposed by these authors whereby the constraint in Equation 5 is appended by the additional constraint

$$h_n(t) = g_n(-t) \quad (6)$$

In other words, the receiver filters are matched filters for the corresponding transmission filter. The minimization condition is changed in this approach to merely state that the out-of-band spectral content of the filters should be zero; no constraints are placed on the in-band amplitude. Although one might think that the constraint in Equation 6 gives optimal noise performance, in practice the relaxation of the transmitter spectral shape specification means that highly nonuniform spectra can arise from this approach. As such, the use of matched filters only optimizes the noise performance given a particular waveform spectrum but does not necessarily give the best possible performance given the power and bandwidth available.

Although neither approach is entirely ideal, they both succeed in satisfying the condition of Equation 5 and therefore producing a set of filters that are suitable in theory for three-dimensional CAP. In fact, both approaches are also easily extensible to higher dimensions. Figure 18

Figure 18: Set of filter responses for three-dimensional CAP (Tang, Thng, and Li 2003), their autocorrelation functions, and their cross-correlation functions

shows an example set of responses for a three-dimensional CAP transmitter (Tang, Thng, and Li 2003). Because the receiver filters are the same as the matched filters, their compliance with Equation 5 can be observed through their autocorrelation functions ($n = m$) and their cross-correlation functions ($n \neq m$). These are also shown in Figure 18. Note that they meet the constraints of Equation 5 by all being zero for time delays that are integer multiples of T except for the autocorrelation functions at zero delay, which are all unity.

Multidimensional CAP Advantages and Disadvantages

At first glance, one might conclude that adding extra dimensions gives the system extra throughput without the need for additional bandwidth or without compromising the noise performance. This is, however, not true; the increase in throughput does not come without cost. It has been observed by Tang, Thng, and Li (2003) that the most significant potential advantage of multidimensional CAP is the relative simplicity in terms of receiver implementation as compared with an equivalent two-dimensional CAP. It can be easier to implement several lower-rate equalizers in parallel rather than two higher-rate ones.

Published work on the subject (up to 2007) focuses on simulations rather than realistic practical experiments. Possible limitations of multidimensional CAP systems in practice have not been reported so far. It is felt that the constraints that the additional dimensions place on the adaptive equalizers will probably compromise their ability to equalize NEXT interference and may affect their performance in multipath environments. It is also likely that the synchronization tolerances required for reliable operation may become tighter for higher dimensions. The received energy from dimensions other than the one to which an equalizer is “tuned” appears between the symbol sampling instants. If the number of dimensions is increased, then the magnitude of this energy also increases and the potential interference that would leak through because of small timing or equalization errors becomes greater.

CONCLUSION

Carrierless amplitude phase modulation has found many uses in high data-rate digital communications and computer-networking systems. The transmitter and receiver architectures are particularly suited to modern digital signal processor-based systems. Although CAP has been largely superseded by discrete multitone systems in many ADSL systems, it is still used in many countries. It also finds use in ATM local area networks.

In many applications, CAP finds favor because of its high bandwidth efficiency and low implementation costs. Where it has been replaced by alternative technologies, this has often been the result of relatively poor performance of CAP against narrowband interference sources.

Recent advances in multidimensional CAP show theoretical promise in terms of further simplifying receiver operation in future systems. It is apparent, however, that researchers must address several technical issues before this becomes a realistic proposition.

GLOSSARY

Adaptive equalizer: An equalizer whose coefficients adapt in order to continually counter the effects of a time-varying channel response.

Asymmetrical digital subscriber line (ADSL): A popular method for providing broadband data services alongside voice communications using existing copper telephone cables.

Asynchronous transfer mode (ATM): A network and data-link layer protocol most commonly used in WAN applications.

Carrierless Amplitude Phase (CAP) modulation: A communications method used in computer networks.

Cross talk: Undesirable coupling of signals from one communications circuit to another.

Cyclostationarity: A characteristic of a signal whose statistical properties vary periodically with time.

Discrete multitone (DMT) modulation: Also known as *orthogonal frequency division multiplexing* (OFDM), a communications method used in some ADSL systems as an alternative to CAP.

Equalizer: A filter used to modify the frequency spectrum of a signal in order to remove or suppress the effects of the channel response.

Far-end cross talk (FEXT): Cross talk caused by signals coupling from a source located at the opposite end of a cable to the receiver.

Finite impulse response (FIR) filter: A digital filter realized by performing a weighted summation of the contents of a shift register. It is equivalent to the mathematical procedure of convolution with a sampled set of coefficients.

Integrated services digital network (ISDN): An early communications standard used to transmit both voice and data signals over standard copper telephone cables.

Intersymbol interference (ISI): An undesirable source of interference whereby one symbol in a modulated data stream overlaps in time with neighboring symbols. It is generally caused by temporal smearing because of the effects of pulse-shaping filters or a nonideal propagation channel.

Least mean squares (LMS): An iterative optimization technique that attempts to minimize the mean square error of a system using a gradient descent algorithm.

Local area network (LAN): A geographically small computer network consisting of several interconnected machines usually located in the same building.

Near-end cross talk (NEXT): Cross talk caused by signals coupling from a source located at the same end of a cable as the receiver.

Quadrature amplitude modulation (QAM): A digital communications technique similar in principle to CAP but differing in the way it is implemented.

Recursive least squares (RLS): An iterative optimization technique used as an alternative to LMS. It generally exhibits faster convergence but higher steady state error than LMS.

Wide area network (WAN): A geographically large computer network consisting of several interconnected machines that may be located in different parts of the world.

INTRODUCTION

In digital communication systems, a key technique is the *modulation scheme*, which maps the digital information into analog waveforms that match the characteristics of the channel. One of the important digital modulation schemes is *minimum shift keying* (MSK), which combines many attractive characteristics, including constant envelope, compact power spectrum, good error rate performance, simple demodulation, and easy synchronization. These features make MSK an excellent digital modulation technique that is suitable for digital links, in which the bandwidth must be conserved and that can utilize efficient transmitter design with nonlinear devices.

MSK was first developed in the late 1960s (Doelz, Heald, and Collins Radio Co. 1961; Buda 1972). Since then, it has been successfully used in many communication fields (Pasupathy 1979). Table 1 highlights notable dates in MSK history.

We begin with a description of MSK, including its mathematical representation and performance. Then we discuss how to realize the MSK modulator; in particular the transmitter and receiver design, as well as synchronization. Similar to MSK, we also discuss the basics and implementation issues for GMSK modulation. Finally, we review the latest development of MSK and GMSK, followed by a short conclusion.

MINIMUM SHIFT KEYING

In this section, we briefly review related modulation techniques such as frequency shift keying and continuous phase frequency shift keying. Then we introduce the mathematical model of MSK and compare its performance with other modulation schemes. Finally, we discuss how to implement the MSK modulation system.

Fundamentals

Mathematical Model

To introduce MSK, we first consider a simpler digital modulation scheme: *frequency shift keying* (FSK). Typically,

Table 1: Brief History of MSK Development

Date	Development
1972	MSK first used by Data Transmission Company (Sullivan 1972)
1972	MSK applied to domestic satellite system by AT&T (Brady 1972)
1977	Canadian communications technology satellite (Taylor et al. 1977)
1981	GMSK technique proposed (Murota and Hirade 1981)
1991	MSK applied to digital European cordless telecommunications (Feher 1991)
Since 1998	GMSK applied to global system for mobile (GSM) communications successfully. MSK and GMSK are attractive digital modulation concepts for B3G.

in one symbol duration, the FSK signal can be expressed as:

$$s_i(t) = \sqrt{\frac{2E_b}{T_b}} \cos(2\pi f_i t), \quad i = 1, 2, \dots, M, \quad 0 \leq t \leq T_b \quad (1)$$

where E_b is the energy per bit, T_b is the bit duration, f_i is the i th carrier frequency, and M is the total number of difference frequencies. Clearly, the waveforms of different carriers have the same energy, and the cross-correlation coefficient of two waveforms is

$$\rho_{km} = \frac{1}{T_b} \int_0^{T_b} \cos[2\pi(f_m - f_k)t] dt \quad (2)$$

If we define Δf as the frequency separation between successive carriers, we can get $f_m - f_k = (m - k)\Delta f$. Therefore

Figure 1: Comparison of (a) FSK with (b) CPFSK signal waveforms

$$\begin{aligned} \rho_{km} &= \frac{1}{T_b} \int_0^{T_b} \cos[2\pi(m-k)\Delta f t] dt \\ &= \frac{\sin[2\pi T_b(m-k)\Delta f]}{2\pi T_b(m-k)\Delta f} \end{aligned} \quad (3)$$

We can see that $\rho_{km} = 0$ when $m \neq k$ and $\Delta f = 1/(2T_b)$. Because $|m - k|$ corresponds to adjacent frequency slots, $\Delta f = 1/(2T_b)$ represents the minimum frequency separation between adjacent frequencies that can guarantee the orthogonality of M possible waveforms (Proakis 1995). To transmit M possible waveforms, a simple solution is to utilize $M = 2^k$ separated oscillators tuned to the desired frequencies and to select one of the M frequencies according to the particular k bit symbol that is to be transmitted in a signal interval of duration kT_b . The output of such a simple system can be seen in Figure 1a, in which we can clearly observe that the phase of FSK signals is discontinuous. Because an FSK system switches abruptly from one oscillator output to another in successive signaling intervals, FSK signal has the relatively large spectral side lobes outside of the main spectral band of the signal, and consequently FSK modulation scheme requires a large frequency band. To resolve this problem, *continuous phase frequency shift keying* (CPFSK) modulation has been proposed, and the corresponding carrier-modulated signal over one bit duration can be expressed as

$$s_i(t) = \sqrt{\frac{2E_b}{T_b}} \cos(2\pi f_i t + \Theta_k) \quad (4)$$

$i = 1, 2, \dots, M, \quad kT_b \leq t \leq (k+1)T_b$

where Θ_k is a continuous function of time and k is zero or a positive integer.

We consider the simplest form of CPFSK—the binary CPFSK—in which $M = 2$. According to Equation 4, the binary CPFSK can be written as

$$s_i(t) = \sqrt{\frac{2E_b}{T_b}} \cos[2\pi(f_c + s_k f_d)t + \Theta_k] \quad (5)$$

$i = 1, 2, \quad kT_b \leq t \leq (k+1)T_b$

with $f_c = (f_1 + f_2)/2$, $f_d = (f_1 - f_2)/2$, where $f_1 > f_2 > 0$ and $s_k = \pm 1$, depending on the input data. To keep continuous phase at time kT_b , $2\pi(f_c + s_{k-1}f_d)kT_b + \Theta_{k-1} = 2\pi(f_c + s_k f_d)kT_b + \Theta_k$ modulo 2π , which results in a recursive expression defining $\Theta_k = \Theta_{k-1} = 2\pi(s_{k-1} - s_k)f_d kT_b$ modulo 2π . Therefore, the variation of the phase over one bit duration can be written as

$$\Theta(t) = 2\pi s_k f_d t + \Theta_k \quad kT_b \leq t \leq (k+1)T_b \quad (6)$$

If we replace the f_d with $h/(2T_b)$, where h is known as the modulation index or deviation ratio, we have

$$\Theta(t) = \pi h s_k \frac{t}{T_b} + \Theta_k \quad kT_b \leq t \leq (k+1)T_b \quad (7)$$

Because $\Theta((k+1)T_b) - \Theta(kT_b) = \pi h s_k$, the phase is increased by πh when $s_k = +1$, and it is decreased by $-\pi h$ when $s_k = -1$. A CPFSK signal has been shown in Figure 1b; clearly, its phase is always continuous at the bit transition instants.

MSK is a special binary CPFSK with $h = 1/2$ in Equation 7, and thus MSK signal can be written as

$$s(t) = \sqrt{\frac{2E_b}{T_b}} \cos \left[2\pi \left(f_c + \frac{s_k}{4T_b} \right) t + \Theta_k \right] \quad (8)$$

$$kT_b \leq t \leq (k+1)T_b$$

Obviously, the frequency separation of MSK is $\Delta f = f_2 - f_1 = 2f_d = 1/(2T_b)$, which is the minimum frequency separation that is necessary to ensure the orthogonality of the signal $s_1(t)$ and $s_2(t)$ over a signaling interval of length T_b . This explains why binary CPFSK with $h = 1/2$ is called *minimum shift keying*.

Using trigonometric functions to expand Equation 8, we have

$$s(t) = \sqrt{\frac{2E_b}{T_b}} \cos(2\pi f_c t) \cos \left(s_k \frac{\pi t}{2T_b} + \Theta_k \right) - \sin(2\pi f_c t) \sin \left(s_k \frac{\pi t}{2T_b} + \Theta_k \right) \quad (9)$$

Without loss of generality, we choose $\Theta_0 = 0$, which results in $\Theta_k = 0$ or π modulo 2π , because $\Theta_k = \Theta_{k-1} + k(s_{k-1} - s_k)\pi/2$. Therefore, the MSK signal can be rewritten as

$$s(t) = \sqrt{\frac{2E_b}{T_b}} a_I(t) \cos \left(\frac{\pi t}{2T_b} \right) \cos(2\pi f_c t) + a_Q(t) \sin \left(\frac{\pi t}{2T_b} \right) \sin(2\pi f_c t) \quad (10)$$

where $a_I(t) = \cos(\Theta_k)$ and $a_Q(t) = -s_k \cdot \cos(\Theta_k)$.

Figure 2 shows various components of the MSK signal defined by Equation 10. Figure 2a shows the binary bit stream $\{a_k(t)\}$ to be sent, which has been broken into staggering of the I-component $\{a_I(t)\}$ and Q-component $\{a_Q(t)\}$ data streams, respectively. Figure 2b shows the sinusoidal shaped in-phase bit stream waveform of the $\{a_I(t)\}$ stream. Figure 2c shows the in-phase signal yielded by multiplying the waveform shown in Figure 2b with the in-phase carrier $\cos 2\pi f_c t$. Similarly, the sinusoidal shaped odd-bits stream and the quadrature signal are shown in Figure 2d and 2e, respectively. Finally, the MSK signal $s(t)$ is shown in Figure 2f, which is the sum of signals shown in Figure 2c and 2e. From Figure 2b and 2d, we can observe that at time kT_b ($k = 0, 1, \dots$), only one of the components (I component or Q component) is 1 while the other is zero. The orthogonality between I component and Q component simplifies detection algorithm, hence it can reduce power consumption in a mobile communication receiver.

If we define $m(t)$ as the sinusoidal pulse, namely,

$$m(t) = \begin{cases} \sin \left(\frac{\pi}{2T_b} t \right) & 0 \leq t \leq 2T_b \\ 0 & \text{otherwise} \end{cases} \quad (11)$$

We can rewrite Equation 10 as

$$s(t) = \sqrt{\frac{2E_b}{T_b}} \sum_{n=-\infty}^{\infty} a_I(t) \cdot m(t - 2nT_b) \cdot \cos(2\pi f_c t) + \sum_{n=-\infty}^{\infty} a_Q(t) \cdot m(t - 2nT_b - T_b) \cdot \sin(2\pi f_c t) \quad (12)$$

where n is an integer. From Equations 10 or 12, it is clear that MSK can be interpreted as being composed of two quadrature data— $a_I(t)$ and $a_Q(t)$ —in an *offset quadrature phase-shift keying* (OQPSK) modulation (Pasupathy 1979) or *staggered quadrature phase shift keying* (SQPSK) (John 1998) signaling system. The *in-phase stream* $a_I(t)$ and the *quadrature stream* $a_Q(t)$ are weighted by sinusoidal functions before modulating the carrier. Consequently, MSK is also a constant amplitude and frequency modulated signal. However, in contrast to pure OQPSK, $a_I(t)$ and $a_Q(t)$ of MSK signal are dependent on each other.

Figure 3 shows the difference between OQPSK and MSK waveforms when an input bit stream is [1 1 0 0 1 1 1]. Clearly, MSK signal has continuous phase, and its phase transition is a type of continuous linear phase shift. Figure 3b shows the OQPSK waveform undergoing a phase shift of $\pm\pi/2$ and its offset of T_b between I component and Q component helps to avoid π phase shift.

It is instructive to sketch the set of phase trajectories $\{\Theta_k\}$ generated by all possible values of the input bit stream $\{a_k\}$. For example, in the case of MSK with binary bits $a_k = 0, 1$, the set of phase trajectories beginning at time $t = 0$ is shown in Figure 4. All of these possible phase diagrams are called a *phase tree*. When the phase tree is reduced modulo 2π , it is called a *phase trellis* (Gulak and Shweddyk 1986). Figure 5 shows an example of a phase trellis for MSK signal, where a phase shift of $+90$ degrees represents a data bit 1 being transmitted and a phase shift of -90 degrees represents a bit 0 being transmitted. From these figures, clearly we can find that the phase at nT_b (n is positive integer) takes a set of discrete values, and over the interval of each bit the phase of the MSK waveform is advanced or retarded by exactly 90 degrees. Therefore, the peak-to-peak frequency shift of the MSK signal equals to its one-half of the bit rate.

Performance

Power spectral density (PSD) is a common characteristic used to compare the bandwidth of communication signals. The unfiltered PSD of a MSK signal can be accurately expressed as (Pasupathy 1979; Morais and Feher 1979)

$$G_{MSK}(f) = \frac{16P_c T_b}{\pi^2} \left(\frac{\cos 2\pi f T_b}{1 - 16f^2 T_b^2} \right)^2 \quad (13)$$

where P_c is the power of the modulated waveform, T_b is the bit duration, and f is the frequency offset of the carrier. For comparison, here we also write out the PSD of OQPSK signal:

$$G_{OQPSK}(f) = 2P_c T_b \left[\frac{\sin 2\pi f T_b}{2\pi f T_b} \right]^2 \quad (14)$$

Obviously, $G_{MSK}(f)$ and $G_{OQPSK}(f)$ are different as shown in Figure 6. It is clear to note that the width of the main lobe of the MSK spectrum is 1.5 times larger than that of the OQPSK spectrum. However, side lobes in MSK fall off faster, which makes MSK more bandwidth efficient.

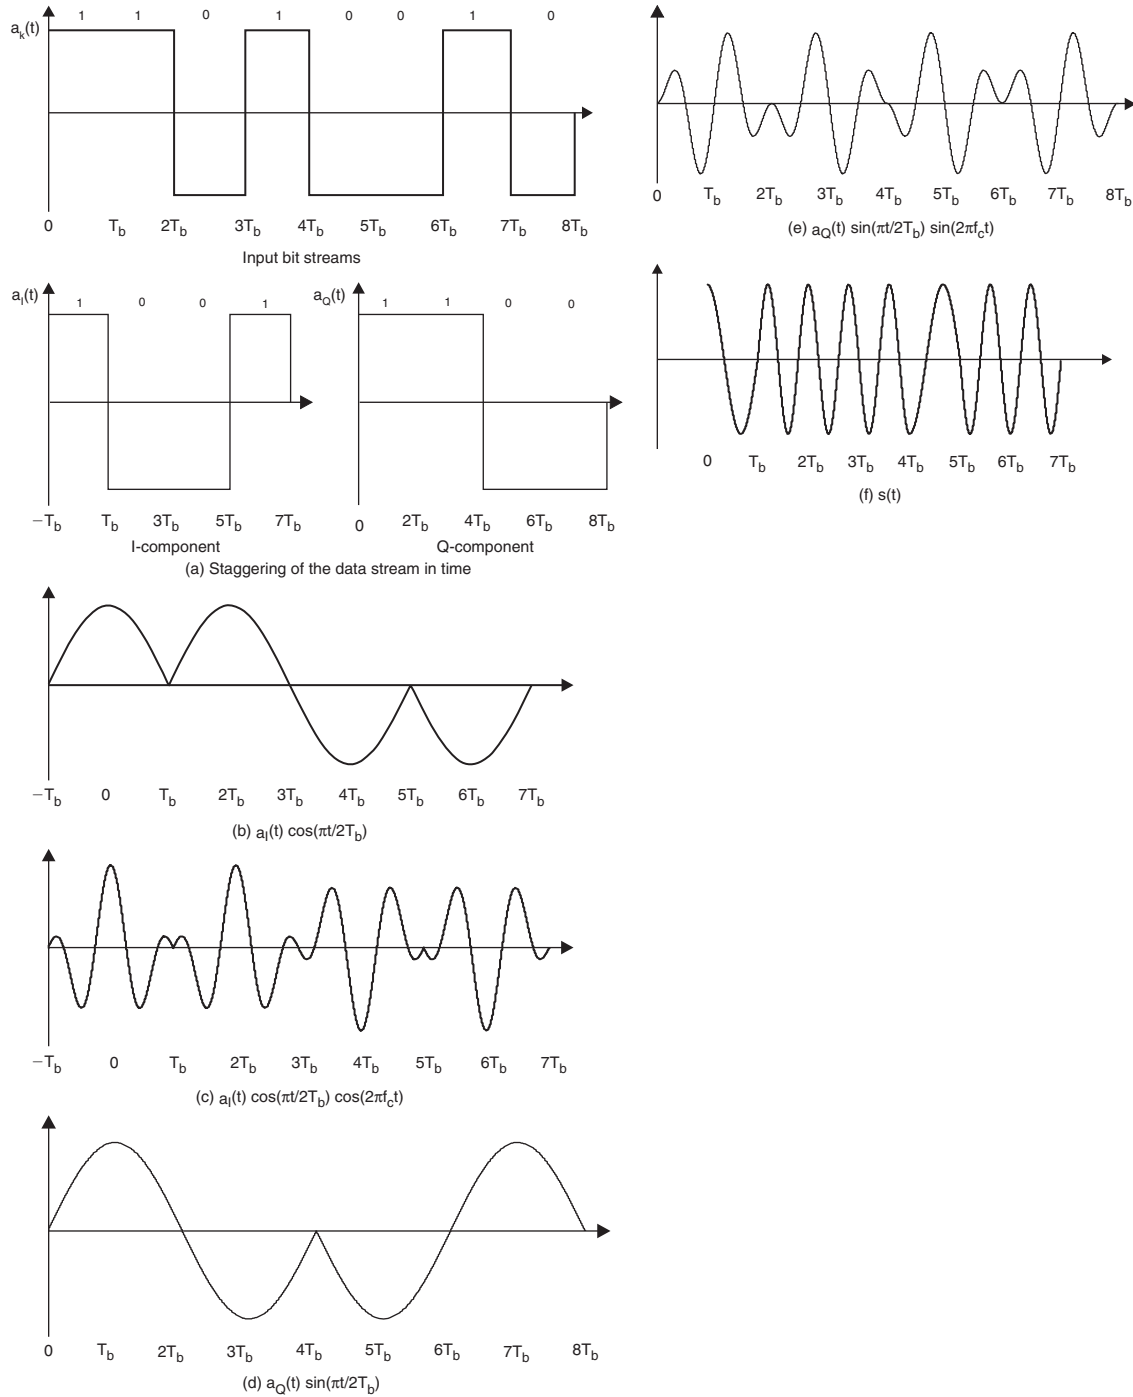

Figure 2: Processing of the composite MSK signal

Another measure of the compactness of a modulation spectrum is bandwidth B , which contains 99 percent of the total power. For MSK, $B \cong 1.2/T_b$; and for OQPSK, $B \cong 8/T_b$ (Gronemeyer and McBride 1976). This indicates that MSK may be spectrally more efficient than OQPSK in wideband links. However, as shown in Figure 6, the MSK spectrum has a wider main lobe than that of OQPSK, which suggests that in narrowband links MSK may not be the preferred modulation scheme. However, with the right filtering in narrowband links, bandwidth efficiency

of MSK can be the same as that of OQPSK (Morais and Feher 1979).

Furthermore, the performance of MSK modem can be generally quantified by measurement of the bit error rate. Simon and Wang have compared the error probability of differential demodulation of MSK to that of limiter discriminator demodulation in *additive white Gaussian noise* (AWGN) and in partial-band noise jamming (Simon and Wang 1983). Masamura and Mason have analyzed the theoretical and experimental validation for differential

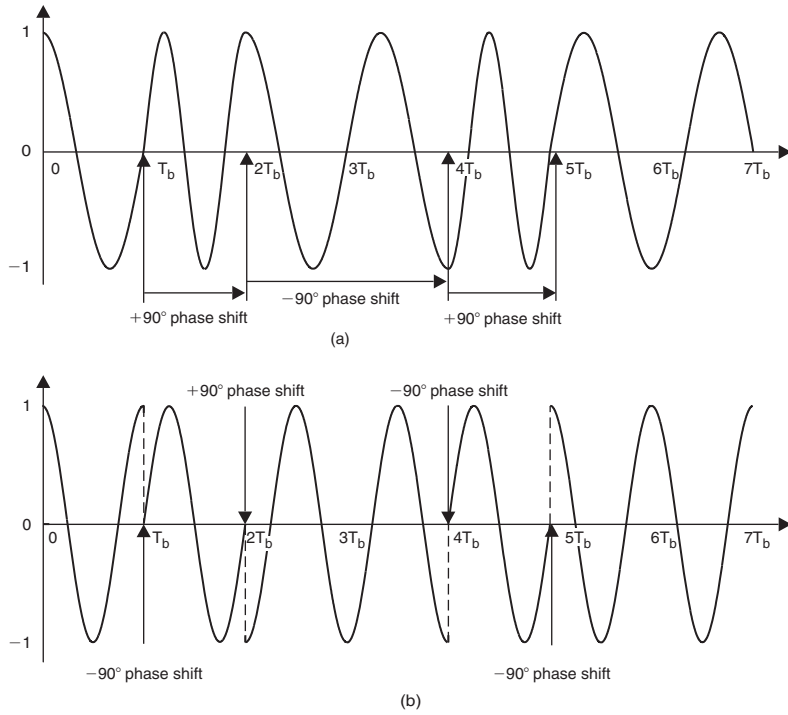

Figure 3: Comparison of (a) MSK and (b) OQPSK signal waveforms

Figure 4: The phase tree of MSK

demodulation of MSK with nonredundant error correction (Masamura et al. 1979; Mason 1987).

In an AWGN channel, the optimum receiver for coherent MSK, which uses correlation demodulation or matched filter demodulation, yields the same BER as that of coherent FSK:

$$P_e \cong Q \left(\sqrt{\frac{2E_b}{N_0}} \right) \quad (15)$$

where P_e is the probability of bit error, $N_0/2$ is the PSD of the AWGN channel, and $Q(t) = \frac{1}{\sqrt{2\pi}} \int_t^\infty e^{-\frac{r^2}{2}} d\tau$. For non-coherent MSK, the optimum receiver for MSK yields the

Figure 5: An example of the MSK phase trellis (the solid line is the phase trajectory path)

Figure 6: Power spectral density of MSK and OQPSK (the solid curve corresponds to MSK, and the dashed curve corresponds to OQPSK)

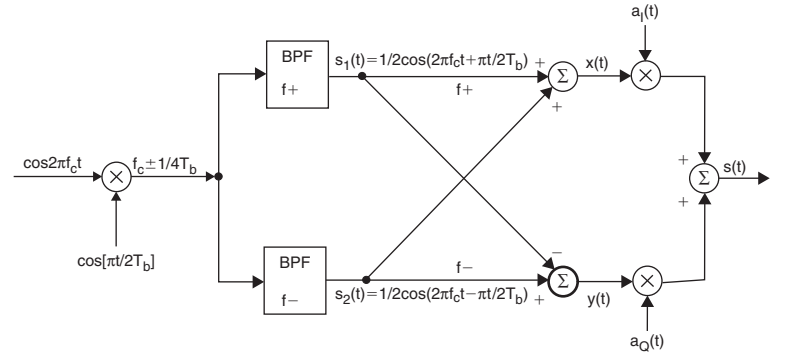

Figure 7: Basic MSK modulator (Pasupathy 1979)

same P_e as that of the noncoherent FSK over the AWGN channel:

$$P_e \approx \frac{1}{2} e^{-\left(\frac{1E_b}{2N_0}\right)} \quad (16)$$

Implementation

Transmitter

Zierner and Ryan examined some methods of implementation of MSK for high data-rate applications (Zierner and Ryan 1983). A typical MSK modulator is shown in Figure 7 (Taylor et al. 1977; Fielding, Berger, and Lochhead 1977; Pasupathy 1979). The multiplier produces two-phase coherent signals at the frequencies $f_+ = f_c + 1/(4T_b)$ ($s_k = +1$) and $f_- = f_c - 1/(4T_b)$ ($s_k = -1$). The biggest advantage of forming *binary frequency shift keying* (BFSK) signals by this method is that the signal coherence and the deviation ratio are largely unaffected by variations in the data rate (Taylor et al. 1977; Pasupathy 1979). The BFSK signals, after being separated by means of *narrow-band pass filters* (NBPF), are combined to form the corresponding I component and Q component. These carriers are then multiplied with the odd and even bit streams

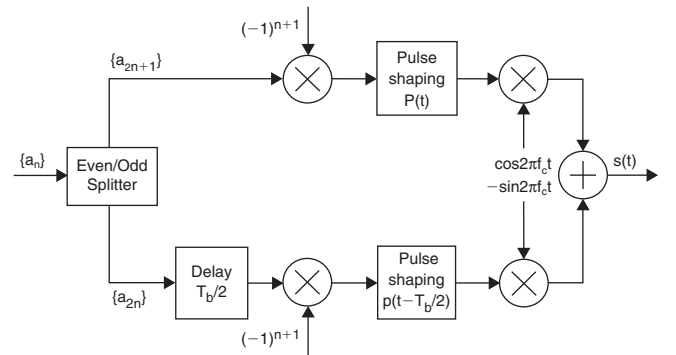

Figure 8: Precoded MSK transmitter

$a_i(t)$ and $a_o(t)$ with T_b offset to produce the MSK-modulated signal $s(t)$ as defined in Equation 10.

As a special modulator, the precoded MSK transmitter is a combined differential decoder with MSK modulator as shown in Figure 8 (Simon, Hinedi, and Lindsey 1995). A compensating differential decoder should be needed following I-component and Q-component demodulation and detection at the receiver when a differential encoder is used in a conventional MSK modulator. Such a

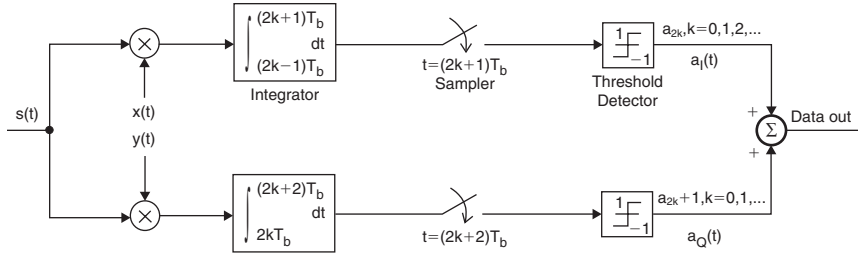

Figure 9: Basic MSK receiver (Pasupathy 1979)

combination of differential encoding at the transmitter and differential decoding at the receiver results in a loss in power performance relative to that obtained by conventional MSK. However, the precoded MSK does not need a differential decoder at the receiver. Therefore, precoded MSK has an improvement in power performance with the same identical spectral as the conventional MSK.

Receiver

A typical MSK receiver is shown in Figure 9. The received signal $s(t)$ is multiplied by the in-phase carrier $x(t)$ and quadrature carrier $y(t)$; they are then followed by the integrate and dump circuits, respectively. The multiplier integrator constitutes the correlation detection, which is an optimum coherent detection operation for a signal in white Gaussian noise without any *intersymbol interference* (ISI). Note that the integration interval is $2T_b$. When $s(t)$ is multiplied by $x(t) = \cos(\pi t/2T_b) \cos(2\pi f_c t)$, the low-frequency component equals $a_I(t)(1 + \cos \pi t/T_b)/4$. Hence, the polarity of the sampler output determines the value of $a_I(t)$. Similarly, the operation on the quadrature channel determines the value of $a_Q(t)$.

Synchronization

Imperfect phase and timing nonsynchronization degrade the MSK signal performance. *Synchronization* is the coordination of occurrences to operate in unison with respect to time and carriers. Figure 10 shows the basic MSK synchronization recovery circuit. The clock signal at one-half of the bit rate is recovered from $s(t)$ and the reference waveforms $x(t)$ and $y(t)$. Although the MSK signal $s(t)$ has no discrete components that can be used for synchronization, it produces strong discrete spectral components at $2f_c + 1/(2T_b)$ and $2f_c - 1/(2T_b)$ after passing

through a *squarer*. This squarer can be defined as squaring both sides of Equation 8—namely,

$$\begin{aligned} s^2(t) &= \cos^2 \left[2\pi f_c t + \frac{S_k \pi}{2T_b} + \Theta_k \right] \\ &= \frac{1}{2} + \frac{1}{2} \cos \left[4\pi f_c t + \frac{S_k \pi}{T_b} t + 2\Theta_k \right] \end{aligned} \quad (17)$$

Note that $2\Theta_k$ becomes either 0 or 2π and therefore drops out. In effect, this squarer doubles the modulation index and produces an FSK signal with $\Delta f = 1/T_b$, which is known as *Sunde's FSK* (Bennett and Rice 1963), and its phase of each tone is a constant. This means that we can lock to each of these tones with a *phase-locked loop* (PLL) and divide each output frequency by two, then produce a pair of reference signals $s_1(t) = \frac{1}{2} \cos[2\pi f_c t + \pi t/(2T_b)]$ and $s_2(t) = \frac{1}{2} \cos[2\pi f_c t - \pi t/(2T_b)]$. Consequently, we can get the sum and difference of the reference signals $s_1(t)$ and $s_2(t)$, respectively:

$$\begin{aligned} s_1 + s_2 &= \frac{1}{2} \cos \left(2\pi f_c t + \frac{\pi t}{2T_b} \right) + \frac{1}{2} \cos \left(2\pi f_c t - \frac{\pi t}{2T_b} \right) \\ &= \cos \left(\frac{\pi t}{2T_b} \right) \cos(2\pi f_c t) = x(t) \end{aligned} \quad (18)$$

$$\begin{aligned} s_1 - s_2 &= \frac{1}{2} \cos \left(2\pi f_c t + \frac{\pi t}{2T_b} \right) - \frac{1}{2} \cos \left(2\pi f_c t - \frac{\pi t}{2T_b} \right) \\ &= \sin \left(\frac{\pi t}{2T_b} \right) \sin(2\pi f_c t) = y(t) \end{aligned} \quad (19)$$

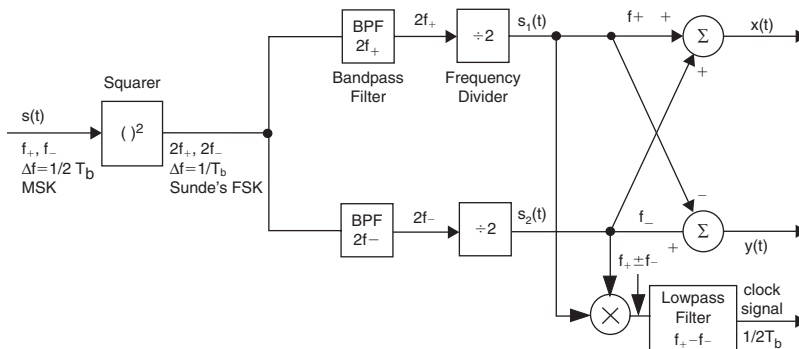

Figure 10: Basic MSK synchronization recovery (Pasupathy 1979)

Figure 11: GSK modulator structure (Borowski and Feher 1995)

Equations 18 and 19 show that the reference carriers of $x(t)$ and $y(t)$ can be obtained from $s_1 + s_2$ and $s_1 - s_2$, respectively. To obtain a clock reference signal, the signal $s_1(t)s_2(t) = \frac{1}{4} \cos\left(2\pi f_c t + \frac{\pi}{2T_b} t\right) \cos\left(2\pi f_c t - \frac{\pi}{2T_b} t\right) = \frac{1}{8}$

$\left[\cos(4\pi f_c t) + \cos\left(\frac{\pi}{T_b} t\right) \right]$ goes through a PLL designed to

run a frequency of $1/(2T_b)$. Therefore, the resultant signal is proportional to $\sin(\pi t/T_b)$, which is the desired timing waveform. This is the reason why the MSK modulation format lends itself to easy self-synchronization.

Summary for MSK

MSK has some excellent properties that make it an attractive alternative when high bandwidth efficiency is required. These characteristics are summarized as follows:

1. MSK is a special type of CPFSK with a frequency deviation equal to one-half of the bit rate, and its modulus envelope is a constant. The continuous phase nature of MSK makes it highly desirable for high-power transmitters driving highly reactive loads.
2. MSK can also be viewed as a form of OQPSK signaling with the Q component delayed by one bit period in which the symbol pulse is a half-cycle sinusoid rather than the usual rectangular form.
3. The phase of the radio frequency carrier at the bit transition instants is continuous. Therefore, MSK can be demodulated with simple synchronization circuits.
4. In wideband communication links, MSK is spectrally more efficient than OQPSK. In narrowband links, it is preferred because of its wider main lobe.

GAUSSIAN MINIMUM SHIFT KEYING

Gaussian minimum shift keying (GMSK) is a frequency modulation scheme that has been widely applied in some of the most prominent communication standards around the world. GMSK improves the spectral efficiency of MSK by using a Gaussian-shaped impulse response filter.

Fundamentals

Mathematical Model

As mentioned in the previous section, MSK modulation has some good properties such as a constant envelope. However, the spectrum of MSK is too loose, and MSK does not satisfy some requirements with respect to out-of-band radiation for some mobile radio (Murota and Hirade 1981). To make the MSK output power spectrum more compact, we can select a *low-pass filter* (LPF) to meet the following conditions: (1) narrow bandwidth and sharp cutoff to suppress high-frequency components, (2) small

overshoot impulse response to prevent excess deviation of the instantaneous frequency, and (3) preservation of an integrated filter output pulse capable of accommodating a 90-degree phase shift to ensure coherent demodulation. A premodulation Gaussian LPF, which satisfies the above requirements, is adopted for GMSK modulation in which the data sequence is passed through a Gaussian LPF filter, and the output of the filter is MSK-modulated (Murota and Hirade 1981).

Figure 11 shows the block diagram of the structure of a GMSK *voltage-controlled oscillator* (VCO) modulator. If the Gaussian filter is left out, one obtains the modulator structure of MSK. First, an antipodal *non-return-to-zero* (NRZ) sequence $b_n \in (-1, 1)$ is converted to a stream of rectangular pulses $r(t) = \sum_n b_n \cdot p(t - nT_b)$, where T_b is the symbol interval. $p(t) = 1$ when $t \in (0, T_b)$, otherwise $p(t) = 0$.

The next operation is to generate the filtered pulse stream

$$g(t) = r(t) * h(t) \quad (20)$$

where $h(t)$ is the impulse response of the Gaussian filter.

Then the phase $\Phi(t)$ of the carrier wave frequency can be obtained by $\Phi(t) = 2\pi f_c \cdot t + 2\pi f_m \cdot \int_0^t g(\tau) d\tau$ around a

carrier frequency f_c , where f_m is the peak frequency deviation and the phase is normalized to 0 at $t = 0$. Therefore, the instantaneous frequency of the modulated signal will be $f(t) = \frac{1}{2\pi} \frac{d\Phi}{dt} = f_c + f_m \cdot g(t)$. It is clear that the mod-

ulated GMSK carrier is determined by f_m , and f_m is determined by the bit rate, just like the MSK signal $f_m = 1/(4T_b)$ (Linz and Hendrickson 1996; Pasupathy 1979).

Finally, a VCO or equivalent digital synthesis method can produce the GMSK signal $s(t) = \cos[\Phi(t)]$. Consequently, the GMSK signal can be written as

$$s(t) = \sqrt{\frac{2E_b}{T_b}} \cos(2\pi f_c t) \cos\left\{2\pi f_m \cdot \int_0^t g(\tau) d\tau\right\} - \sqrt{\frac{2E_b}{T_b}} \sin(2\pi f_c t) \sin\left\{2\pi f_m \cdot \int_0^t g(\tau) d\tau\right\} \quad (21)$$

For GMSK, $h(t)$ is a key parameter, and its Fourier transform pair (Adachi and Ohno 1988) is

$$H(f) = e^{-\alpha^2 f^2} \quad (22)$$

$$h(t) = \frac{\sqrt{\pi}}{\alpha} e^{-\frac{\pi^2 t^2}{\alpha^2}} \quad (23)$$

Figure 12: Shapes of $g(t)$ with different $B_b T_b$

The term α is defined as (Linz and Hendrickson 1996)

$$\alpha = \frac{\ln(2)}{2(B_b T_b \cdot 2\pi f_b)^2} \quad (24)$$

where $B_b = B_{3dB}$ and B_{3dB} is 3-dB bandwidth, $f_b = 1/T_b$. Consequently, the typical pulse response $g(t)$ can be written as

$$g(t) = \left\{ Q \left[2\pi B_b \frac{t - T_b}{\sqrt{\ln 2}} \right] - Q \left[2\pi B_b \frac{t + T_b}{\sqrt{\ln 2}} \right] \right\} \quad (25)$$

where $Q(t) = \frac{1}{\sqrt{2\pi}} \int_t^\infty e^{-\frac{\tau^2}{2}} d\tau$.

$B_b T_b$ is a common design parameter of the GMSK modulator. Figure 12 shows different shapes of $g(t)$ with different $B_b T_b$. When $B_b T_b = \infty$, the GMSK is the same as the MSK.

Figure 13 shows a GMSK signal with $B_b T_b = 0.2$. It is clear that Gaussian filtered pulses overlap each other, giving rise to ISI (Diana and Tien 2001). Therefore, GMSK has a more compact spectrum than MSK. However, the GMSK has the more available frequency spectrum as a cost of increased ISI (Grellier and Comon 1998; Huang, Fan, and Huang 2000). Large ISI allows the spectrum to be more compact, but it also makes the demodulation more difficult.

An *eye diagram* is a simple and convenient tool for studying the effects of ISI for GMSK modulation as shown in Figure 14. The effect of ISI is a reduction of the eye opening and an increase in the number of paths in the eye diagram. The eye of the instantaneous frequency is relatively poorer in comparison to the I component and the Q component. This indicates that extracting modulation information from the instantaneous frequency would

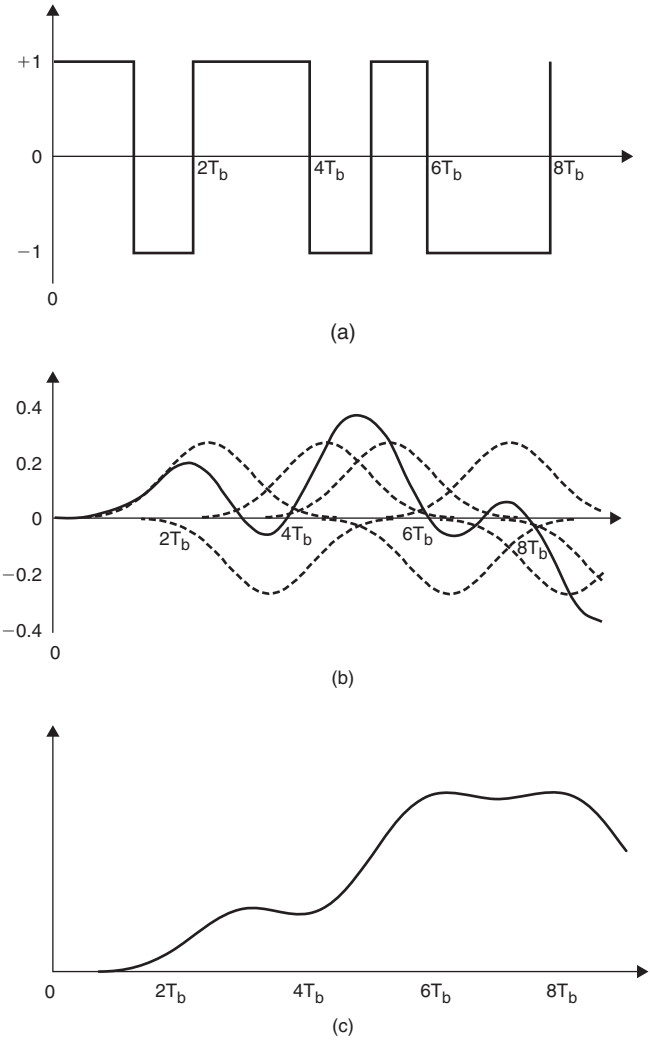

Figure 13: Processing of the composite GMSK signal with $B_b T_b = 0.2$ —(a) input bit stream, (b) output filtered pulse (solid curve; the dashed curve corresponds to the filtered pulse for every bit), and (c) continuous phase

Figure 14: Eye diagrams of GMSK with $B_b T_b = 0.25$ —(a) and eye diagram of the I component; (b) eye diagram of the Q component; (c) eye diagram of instantaneous frequency

Figure 15: Phase trajectories for GMSK with $B_b T_b = 0.25$

yield rather poor performance, and high $B_b T_b$ trades the spectral efficiency with the lower the level of ISI.

It is known that the phase transition of MSK is linearity in every bit duration. However, the phase transition of GMSK is nonlinearity. We call curves of phase transition *phase trajectories* as shown in Figure 15. A Gaussian premodulation filter smooths the phase trajectory of the MSK signal to limit instantaneous frequency variations, which results in a GMSK signal with a much narrower bandwidth. Further, one fundamental concept in Laurent's work states that any phase modulator can be approximated using a set of amplitude modulators, where the phase-shaping filter of the phase modulator is replaced by an equivalent set of filters for the amplitude modulators. For GMSK, the first filter is the most significant pulse, and more than 99 percent of the energy is contained in it. Hence, GMSK can be well approximated

Figure 16: Four possible basic paths in the GMSK phase trajectories

by only using the first term of the Laurent expansion (Laurent 1986).

In fact, for GMSK signals, all state transition paths in the phase trajectories can be generated from four basic paths; these are labeled P_0 to P_3 in Figure 16 (Hellosoft 2002).

Performance

Figure 17 displays the output-normalized spectra of GMSK signals versus the normalized frequency difference from the carrier center frequency with different $B_b T_b$. As $B_b T_b$ decreases, the side-lobe levels fall off rapidly, causing an increase in bandwidth efficiency, which

Figure 17: Power spectral density of GMSK (Murota and Hirade 1981)

Figure 18: Fractional power ratio of GMSK (Murota and Hirade 1981)

means that small $B_b T_b$ are desirable to achieve good spectral efficiency.

Figure 18 shows the fractional power ratio of GMSK versus the normalized bandwidth. For GMSK, when $B_b T_b = 0.25$ and 0.5 , 99.0 percent of the signal powers are contained in a bandwidth of $0.86/T_b$ and $1.04/T_b$, respectively. When $B_b T_b = 1.0$, the graph yields a wider spectrum, indicating a loss in power efficiency (Mandayam 2005).

Similar to MSK, the performance of GMSK modem can be generally quantified by measurement of BER. The

Figure 19: Static BER performance (Murota and Hirade 1981)

static BER performance in the nonfading environment can be approximated as (Murota and Hirade 1981)

$$P_e \cong Q\left(\sqrt{\frac{2\alpha E_b}{N_0}}\right) \quad (26)$$

where $Q(t) = \frac{1}{\sqrt{2\pi}} \int_t^\infty e^{-\frac{\tau^2}{2}} d\tau$ and α has been defined in Equation 24. Compared to MSK, it is clear that $p_e^{GMSK} > p_e^{MSK}$.

This arises from the trade-off between power and bandwidth efficiency: GMSK can achieve better bandwidth efficiency than MSK at the cost of power efficiency.

Figure 19 shows experimental results for static BER performance in the nonfading channel, where the normalized 3-dB down bandwidth $B_b T_b$ of the predetection Gaussian NBPf is a nearly optimal 0.63. When $B_b T_b$ is greater than 0.63, the degradation caused by premodulation filtering remains mild (Ishizuka and Yasuda 1984).

For high SNR, the BER of a GMSK signal transmitted in an AWGN channel is approximated as (Asano and Pasupathy 2002)

$$P_e = \frac{1}{2} \operatorname{erfc}\left(\sqrt{\frac{d_{\min}^2 E_b}{2N_0}}\right) \quad (27)$$

where $\operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2} dt$ and d_{\min} is the normalized

minimum Euclidean distance. For GMSK modulation, the approximate maximum of d_{\min} is $\sqrt{2}$, which corresponds to the performance of optimal antipodal signaling (Murota and Hirade 1981).

However, when the modulated GMSK signals transmitted in a quasi stationary slow Rayleigh fading channel, the dynamic BER can be approximated as (Murota and Hirade 1981)

$$P_e(\Gamma) \cong \frac{1}{2} \left(1 - \sqrt{\frac{\alpha\Gamma}{\alpha\Gamma + 1}} \right) \cong \frac{1}{4\alpha\Gamma} \quad (28)$$

where Γ is the average SNR.

Implementation

Transmitter

Some existing methods can implement GMSK modulation for high data rate applications as follows:

1. The first method is to select the frequency deviation of CPFSK and make it the minimum possible and then filter the baseband modulating signal with a Gaussian filter (Linz and Hendrickson 1996). Therefore, it requires that the modulation index of the VCO exactly equal 0.5. However, the modulation index of the conventional VCO-based transmitter drifts over time and temperature, so it is hard to keep the center frequency within the allowable value under the restriction of maintaining the linearity and the sensitivity for the required frequency modulation (Murota and Hirade 1981).
2. Another attractive method is a *polar modulator*, and its principal design issue is the need for precise matching of the amplitude and phase delays through the feedback loops (McCune and Sander 2003). A polar modulator architecture has been proposed to avoid the external radio frequency filters that would likely be necessary with other transmitter topologies and for compatibility with existing *global system for mobile*

(GSM) communications transmitters for an efficient dual-mode solution (Sander, Schell, and Sander 2003). Meanwhile, a system-level analysis of a polar modulator for GMSK reveals that inadequate bandwidths in the phase modulation and amplitude modulation paths result in spectral regrowth, which can violate the transmit mask requirement as imposed by the standard (Elliott et al. 2004).

3. The third method is to employ a quadrature baseband process followed by a quadrature modulator (Ishizuka and Hirade 1980). With this implementation, the modulation index must be maintained at exactly 0.5.

A typical PLL GMSK modulator is shown in Figure 20; a $\pi/2$ -shift BPSK modulator is followed by a suitable PLL phase smoother. The transfer characteristics of this modulator can ensure that the output power spectrum satisfies the required condition (Murota and Hirade 1981).

Receiver

Similar to MSK, a GMSK signal also can be demodulated either differentially or coherently depending on the performance and complexity requirements. For an orthogonal coherent detector, it is difficult to recover the reference carrier and the timing clock. The most typical method is *de Buda's modulator* (De Buda 1972) as shown in Figure 21. In this demodulator, the reference carrier is recovered by dividing by four the sum of the two discrete frequencies contained in the frequency doubler output; the timing clock is directly recovered by their difference.

Coherent demodulation is common in GMSK systems (e.g., the GSM). It requires knowledge of the reference phase or exact phase recovery, local oscillators, and the PLL and carrier recovery circuits. Thus, the complexity and cost of the demodulator will be increased. Coherent demodulation is also required to facilitate linear equalization, which is necessary to compensate ISI caused by the multipath effect and the premodulation and predetection filtering (Laster 1997). The performance of coherent demodulation may degrade in fading channels because of imperfect tracking of the received signal phase.

Figure 20: PLL-type GMSK modulator

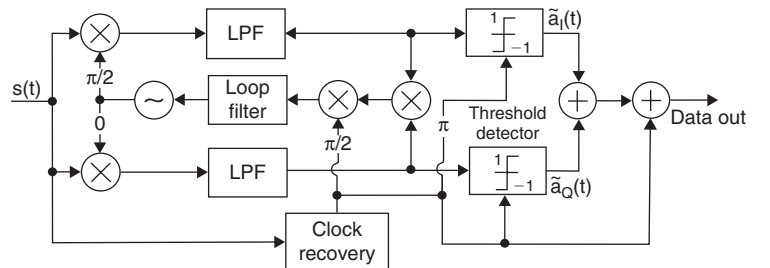

Figure 21: Coherent detector for GMSK

However, noncoherent demodulation is generally less expensive and easier to build than coherent demodulation because it does not need to generate the coherent signal. Therefore, noncoherent demodulation is often preferable, although it can degrade performance under certain channel conditions. Several types of noncoherent demodulation exist, including the differential demodulator and the limiter discriminator (Simon and Wang 1983).

Summary for GMSK

Although GMSK can be generated from MSK, it still has its own characteristics as follows:

1. GMSK modulation focuses on phase as the modulation variable; it turns out that the GMSK is superior in terms of its spectral efficiency.
2. The phase of the GMSK signal is continuous and smoothed by a Gaussian filter. Therefore, GMSK has a more compact spectrum than MSK. However, it suffers more ISI.
3. The degree of Gaussian filtering is expressed by $B_b T_b$. Low values of $B_b T_b$ create significant ISI. When $B_b T_b$ is less than 0.3, an ISI combating mechanism is required.
4. GMSK has a main lobe 1.5 times that of MSK.

EXTENSIONS OF MSK AND GMSK

When MSK is combined with partial response signaling, such as a Gaussian filter, the communication system can achieve more spectral efficiency. However, when phase transitions are spread over several symbol periods, the complexity of the demodulator will increase. Especially when the channel has fixed bandwidth, the increased spectral efficiency is required only for high symbol-rate transmission. When a low-rate data stream is submitted, a receiver with less complexity can complete the transmission. Therefore, it is critically important how to select a reasonable trade-off among bandwidth and system complexity and performance of the modulation through the judicious choice of the modulation parameters. To obtain high performance with low complexity, MSK and GMSK have recently been extended to *multi-amplitude MSK* (MAMSK) (Simon 1976; Weber, Stanton, and Sumida 1978), *optical MSK* (OMSK) (Sakamoto, Kawanishi, and Izutsu 2005), *pulse-driven GMSK* (PDGMSK) (Hetling

and Rhodes 1998), and N-GMSK (Javornik, Kandus, and Burr 2001).

Multi-Amplitude MSK

Just as the name multi-amplitude MSK implies, MAMSK signals can be considered as the superposition of some MSK signals. For example, a two-level MAMSK signal can be expressed as

$$s(t) = 2A \cos[2\pi f_c t + \phi_1(t : I)] + A \cos[2\pi f_c t + \phi_2(t : J)] \quad (29)$$

where $\phi_2(t : I) = \frac{\pi}{2} \sum_{k=-\infty}^{n-1} I_k + \frac{\pi}{2T_b} I_n(t - nT_b)$, $nT_b \leq t \leq (n+1)T_b$, $\phi_2(t : J) = \frac{\pi}{2} \sum_{k=-\infty}^{n-1} J_k + \frac{\pi}{2T_b} J_n(t - nT_b)$, $nT_b \leq t \leq (n+1)T_b$, I_k and J_k are the function of the information sequence (Simon 1976; Proakis 1995). Therefore, MAMSK still keeps the phase continuity property, and it can provide high spectral efficiency. However, its amplitudes of the constituent signals are not equal (as shown in Figure 22), and this prevents the phase trajectory from passing through the origin.

When two orthogonal MSK signals are superposed, we call this special type of MAMSK an *orthogonal MSK* (Ahmed 2002). Consequently, the orthogonal MSK signal can be demodulated using a receiver architecture similar to the parallel receiver architecture for MSK. The only difference is that two correlators for MSK receiver are replaced with four correlators for orthogonal MSK receiver. Also, the performance of orthogonal MSK is worse than MSK or BPSK, although they are orthogonal.

Optical MSK

In optical communication systems, it is important to transmit data with a more compact spectrum to increase spectral efficiency and improve dispersion tolerance in the optical links. It is found that the synchronous control technique cannot offer the condition required for the MSK format, where frequency deviation is $1/(4T_b)$ (Sakamoto, Kawanishi, and Izutsu 2005). To solve this problem and realize external modulation in MSK format, OMSK has been proposed to achieve continuous-phase modulation with a narrower frequency deviation, $1/(4T_b)$.

Figure 22: Constellation diagrams of the MAMSK signal—(a) constituent signals have equal amplitude; (b) constituent signals have unequal amplitude

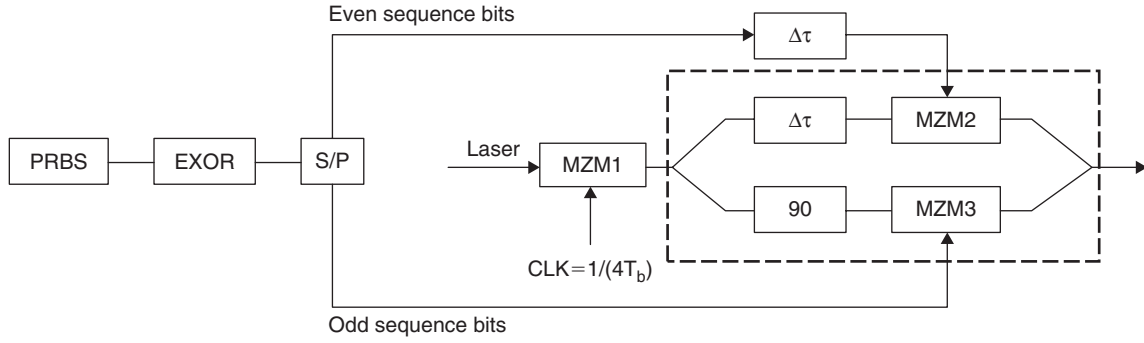

Figure 23: The basic structure of the OMSK modulator

Figure 24: PDGMSK signal modulator

Figure 23 shows the basic structure of the OMSK modulator (Jinyu et al. 2005). First, a *pseudo-random binary sequence* (PRBS) is precoded using an *exclusive OR* (EXOR) gate and then separated by a *serial-to-parallel* (S/P) converter to form the odd-numbered-bit and even-numbered-bit sequences for driving two *Mach-Zender modulators* (MZM)—namely, MZM3 and MZM2, respectively.

The first MZM (MZM1) is used for *carrier suppressed return-to-zero* (CSRZ) pulse generation, which is driven by a clock signal with a frequency of $1/(4T_b)$ and is biased at the null point. Then the CSRZ pulses are fed into the second modulator for MSK modulation, which consists of two arms. The upper arm has a one-bit delay, $\Delta\tau = 1T_b$, and MZM2. The lower arm has a 90-degree phase shifter and MZM3. MZM2 and MZM3 are biased at the null point and driven by two data streams of even bits and odd bits, respectively. This driving condition provides either π or 0 phase shift in each arm according to the values of the bit streams.

Therefore, in the OMSK-modulated signal, the phase of all of the even-numbered bits are either 0 or π , while the phase of all of the odd-numbered bits are either $\pi/2$ or $3\pi/2$. The 1 bit is modulated with $\Phi_n = \Phi_{n-1} = \pi/2$, but $\Phi_n = \Phi_{n-1} = \pi/2$ for bit 0.
